Preface

The AIEE *Transactions* for 1959 (volume 78) is published in three parts: Part I. Communication and Electronics; Part II. Applications and Industry; and Part III. Power Apparatus and Systems. (Part III is divided into two parts: III–A, consisting of pages 1–976; III–B, consisting of pages 977–1870. The Index for both parts appears at the end of III–B.) The papers in each of the three parts are classified according to subject matter as follows:

Part I. Communication and Electronics

Aircraft and Flight Test Instrumentation
Basic Sciences
Broadcasting
Communication Switching Systems
Communication Theory
Computing Devices
Data Communication
Electrical Insulation
Electrical Techniques in Medicine and Biology
Electronic and High Frequency Instruments
Electronics
Indicating and Integrating Instruments
Magnetic Amplifiers
Nucleonic and Radiation Instrumentation
Nucleonics
Radio Communication Systems
Recording and Controlling Instrumentation
Semiconductor Metallic Rectifiers
Solid State Devices
Special Instruments and Auxiliary Apparatus
Telegraph Systems
Telemetering
Wire Communication Systems

Part II. Applications and Industry

Aero-Space Transportation
Chemical Industry
Domestic and Commercial Applications
Electric Heating
Electric Welding
Feedback Control Systems
General Industry Applications
Industrial and Commercial Power Systems
Industrial Control
Industrial Power Rectifiers
Land Transportation
Marine Transportation
Metal Industry
Mining Industry
Petroleum Industry
Production and Application of Light

Part III. Power Apparatus and Systems

Insulated Conductors
Power Generation
Power System Communications
Protective Devices
Relays
Rotating Machinery
Substations
Switchgear
System Engineering
Transformers
Transmission and Distribution

Research
Safety
Standards

Each part has been indexed separately in the back of that particular part. The three parts are not cross-referenced; hence the user should determine first whether the subject matter of the paper desired is in the field of communication and electronics, applications and industry, or power apparatus and systems. Papers are listed in the subject index under several key words in the titles. The original numbers assigned to the papers are given in the author index. Volume 78 contains the technical papers and related discussions presented at these meetings:

1. Winter General Meeting, New York, N. Y., February 1–6, 1959.
2. Southeast and South Central District Meeting, Atlanta, Ga., April 8–10, 1959.
3. East Central District Meeting and Rubber and Plastics Conference, Akron, Ohio, April 22–24, 1959.
4. Empire District Meeting, Syracuse, N. Y., April 29–May 1, 1959.
5. Middle Eastern District Meeting, Baltimore, Md., May 19–21, 1959.
6. Summer and Pacific General Meeting and Air Transportation Conference, Seattle, Wash., June 21–26, 1959.
7. AIEE-IRE Nonlinear Magnetics and Magnetic Amplifiers Conference, Washington, D. C., September 23–25, 1959.
8. Fall General Meeting, Chicago, Ill., October 11–16, 1959.

Statements and opinions given in the papers and discussions published in *Transactions* are the expressions of the contributors for which the American Institute of Electrical Engineers assumes no responsibility.

1. Technical Subject Index

A-C Magnets from Simple Models, Inductance of. Douglas, Voith....562–8; disc. 568

A-C Resistance of Solid Magnetic Wires, The. Gohar....912–16

A-C Shocks of Varying Parameters Affecting the Heart. Kouwenhoven, Knickerbocker, Chesnut, Milnor, Sass....163–7; disc. 167

Aging Calculations, Mathematics of Insulation-. Whitman, Whitman....308–16; disc. 316

Aircraft Electric Systems, Transistor-Magnetic Control Circuits for. Pratt....643–50

Algebra of Sequential Logic—Matrix Logic III, Matrix. Schubert....1074–9

Algebraic Matrix Equations, Electronic Network Synthesis of Linear. Horn, Honnell....1028–32

Allentown-Bethlehem, Pa., City-Wide Personal Signaling at. Kraus....52–5

Alloy Junction Transistors Above Rated Conditions, Effects of Operation of Germanium. Spradlin....346–52

Alternating Magnetic Fields, Conducting Sphere in. Poritsky....937–42

Analog Conversion, Magnetic Amplifier Binary-to-. Danylchuk, Katz....909–12

Analog Data, Measurements of Narrow-Band Noise on Telephone Facilities in Connection with. Edson, Froehlich, Townley....83–6

Analog Division Circuit. McMurray....606–12

Analog of Heat Flow in Power Transistors, An Electric. Reese, Grannemann, Durant....640–3

Analog Simulations, Application of Finite Integral Transforms to. Karplus, Stephens....152–5

Analogs and Duality, Electromechanical Impedance. Swift....81–3

Analysis and Design of a Transistor Linear-Delay Circuit. Nanavati....577–80

Analysis of Magnetic Amplifiers Using a Resistive Reactor Model. Frankenthal....850–7; disc. 857

Analysis of Magnetic Amplifiers With Diodes. Johannessen....485–504

Analysis of Magnetic Amplifiers Without Diodes. Johannessen....471–85

Analysis of Series-Connected Saturable Reactor with Capacitive Loading and Finite Control Resistance by Use of Difference Equations. Bourne, Salihi....461–71

Analysis of the Effects of an Electric Field on the Charging of Fine Particles, A Theoretical. Murphy, Adler, Penney....318–26

Annular-Plate Capacitors, Subarea Determination of the Capacitance of Cocentric. Reitan, Higgins....1002–05

Anomaly in Residual Polarization of $BaTiO_3$ Ceramics, On the. Saito, Yamanaka....70–6

Antenna, The Design of the Corner-Reflector. Neff, Tillman....293–5

Apparatus as Compared with Insulation Material Tests, Functional Life Tests of. Manning....1107–10; disc. 1110

Application of a New Carrier Telegraph System. Collins, Pitts....1009–16; disc. 1016

Application of Finite Integral Transforms to Analog Simulations. Karplus, Stephens....152–5

Application of Telegraph Techniques in Data Transmission. Boggs, Boughtwood....336–40

Approach to the Study of Automatic Target Tracking, An. Pode....806–11

Approach to Training Telephone Engineers, A New. Burnett, Adams....572–6; disc. 576

Artificial Respiration Techniques, A Comparison of Mouth-to-Mouth and Manual. Gordon, Frye....86–91

Assurance Program, Quality. Hulnick, Harding, Rowinski....326–35

Asynchronous Multiplexing. Taylor....1054–62

Automatic Programing Techniques for Solving Engineering Problems, The Use of. Carleton, Chackan, Martin....596–601; disc. 601

Automatic Regulators with Self-Balancing Magnetic Amplifiers. Geyger....433–8

Automatic Target Tracking, An Approach to the Study of. Pode....806–11

Automatic Teletypewriter Switching System, A Small. Shimmin, Vanderlippe, Whitman....959–64

B

Basic Concepts of Multidimensional Space Filters. Kron....554–61

(Basic Sciences) A New Direct Matrix Inversion Method. Shipley, Coleman....568–70; disc. 570

(Basic Sciences) Conducting Sphere in Alternating Magnetic Fields. Poritsky....937–42

(Basic Sciences) Criteria and Tests for Realizability of the Inductance Matrix. Tokad, Reed....924–6

(Basic Sciences) Current Distribution in the Cylindrical Source Plane-Electrode Configuration. Comstock, Williams....252–6

(Basic Sciences) Eddy-Current Losses in Solid and Laminated Iron. Agarwal....169–79; disc. 179

(Basic Sciences) Effects of Ultrahigh Temperature on Magnetic Properties of Core Materials. Pasnak, Lundsten....1033–8; disc. 1038

(Basic Sciences) Electromechanical Impedance: Analogs and Duality. Swift....81–3

(Basic Sciences) Electronic Network Synthesis of Linear Algebraic Matrix Equations. Horn, Honnell....1028–32

(Basic Sciences) Inductance of A-C Magnets from Simple Models. Douglas, Voith....562–8; disc. 568

(Basic Sciences) Mixed Transcendental and Polynomial Transforms. Smith....786–95

(Basic Sciences) Recurrence Relations in the Solution of a Certain Class of Nonlinear Systems. Wolf....830–4; disc. 834

(Basic Sciences) Some Multihorned Dilemmas in the Magnetic Field. Avcin....1087–95

(Basic Sciences) Spectral Output of Piecewise Linear Nonlinearity. Smith....543–9

(Basic Sciences) Statistical Spectral Output of Power Law Nonlinearity. Smith....535–43

(Basic Sciences) Subarea Determination of the Capacitance of Cocentric Annular-Plate Capacitors. Reitan, Higgins....1002–05

(Basic Sciences) The A-C Resistance of Solid Magnetic Wires. Gohar....912–16

(Basic Sciences) The Characteristic Impedance and Phase Velocity of a Shielded Helical Transmission Line. Kirschbaum....444–50

(Basic Sciences) The Computation of Correlation and Spectral Functions by Orthogonal Filtering. Gilbert....954–9

(Basic Sciences) The Effect of Flux Distribution on Iron Losses. Schindler....1069–74

(Basic Sciences) The General Form of Some Common Network Theorems. Adamson, El-Sobki....991–5; disc. 995

(Basic Sciences) The Optimum Transmission-Line Pulse Transformer. Young, Schatz, Woodford....220–3

(Basic Sciences) The Transient Response of Tapered Transmission Lines. Young, Schatz, Woodford....223–8; disc. 228

(Basic Sciences) Two-Oscillator Scan Stability. Joseph....1022–8

$BaTiO_3$ Ceramics, On the Anomaly in Residual Polarization of. Saito, Yamanaka....70–6

Bethlehem, Pa., City-Wide Personal Signaling at Allentown-. Kraus....52–5

Binary-to-Analog Conversion, Magnetic Amplifier. Danylchuk, Katz....909–12

Bridge for Surface Temperature Measurement, An Impedance. Mouly....388–92; disc. 392

Bridge Magnetic Amplifier, Theory of 3-Phase. Storm, Flairty:
  Part I....878–95

Brightness Intensification in Fluoroscopic Image Intensifiers, Standards for Measurement of. Lusby....504–05; disc. 506

Burial Wire, The Design and Manufacture of Direct. Robb, Roberts....662–6; disc. 666

C

Cable, Design of Polyethylene-Insulated Multipair Telephone. Windeler....736–9

Cable, More About Nonarmored Submarine. Lawton....367–9

Cable Sheath for Telephone Exchange Cable, Manufacture of Composite. Hughes....650–4

Cable Simulation Networks, Synthesis of. DeMonte....682–6

Cables at Voice and Carrier Frequencies, Transmission Properties of Polyethylene-Insulated Telephone. Eager, Jachimowicz, Kolodny, Robinson....618–39; disc. 639

Calculations, Mathematics of Insulation-Aging Whitman, Whitman....308–16; disc. 316

Calibration of Precision Voltage Dividers, A Method for. Pinckney....182–5

Calling System, The 83B1 Teletypewriter Selective-. Smith, Votaw, Whitman....119–24

Capacitance of Cocentric Annular-Plate Capacitors, Subarea Determination of the. Reitan, Higgins....1002–05

Capacitances in Magnetic Amplifiers, The Winding. Johansen....702–07

Capacitive Loading and Finite Control Resistance by Use of Difference Equations, Analysis of Series-Connected Saturable Reactor with. Bourne, Salihi....461–71

Capacitively Coupled Magnetic Amplifiers. Collins....707–12

Carbon-Film Resistors after 12,000 Hours of Operation, Life Characteristics of. Braner, Easterday..201–07

Carrier System, The K24A Syncroplex Telephone. Coetsee, Curtis, Halina....1044–54; disc. 1054

Carrier Systems Up to 156 Kc, A Transposition System for. Kirkland....612–14

Carrier Telegraph System, Application of a New. Collins, Pitts....1009–16; disc. 1016

Carrier Telegraph System, Design Features of a New Frequency Shift. Stephens....927–34

Carrier Telegraph Terminal, A Transistorized 20-Channel. Grybowski, Vieth....260–5

CCITT Recommendations for Multichannel Radio Relays and White Noise. Parry....107–17

Central Office Area, Indialing to PBX Extensions:. Application in a Step-by-Step. Schleinkofer....549–54

Ceramic Hydrogen Thyratrons, Factors Leading to the Development of. Price, Coolidge....76–80

Ceramics, On the Anomaly in Residual Polarization of $BaTiO_3$. Saito, Yamanaka....70–6

Challenge of Universal Mobile Communications, The. Culbertson....973–9

Characteristic Impedance and Phase Velocity of a Shielded Helical Transmission Line, The. Kirschbaum....444–50

Characteristics Affected by Control-Circuit Resistance, Graphical Analysis of Full-Wave Magnetic Amplifier Control. Murakami, Kikuchi....526–30

Characteristics of Carbon-Film Resistors after 12,000 Hours of Operation, Life. Braner, Easterday....201–07

Charged Magnetic Pulse Modulator, D-C. Manteuffel, Cooper....843–50

Charging of Fine Particles, A Theoretical Analysis of the Effects of an Electric Field on the. Murphy, Adler, Penney....318–26

Circuit, Analog Division. McMurray....606–12

Circuit, Analysis and Design of a Transistor Linear-Delay. Nanavati....577–80

Circuit as Applied to a Conference Repeater, A New Dynamic Impedance Matching. Grandstaff....751–5

Circuit-Field Problems, The Use of Iterated Laplace Transformations in the Solution of Combined. Mulligan....506–11

Circuit for Transformers in Which Nonlinear Effects Are Present, An Equivalent. Lord.580–5; disc. 586

Circuits—A Classification of Half-Wave and Full-Wave Nonreversible and Reversible Self-Saturating Circuits, Magnetic Amplifier. McMurtrie....739–51

Circuits, A Comparison of Sequential and Iterative. McCluskey....1039–44

Circuits for Aircraft Electric Systems, Transistor-Magnetic Control. Pratt....643–50

Circuits, Shunt-Coupled Magnetic-Amplifier. Hubbard....124–31

Circuits, The Numerical Graphical Method in the Design of Multiterminal Switching. Scheinman....515–19

Circular Polarization Duplexer for Millimeter Waves, A. Fellers....934–7

City-Wide Personal Signaling at Allentown-Bethlehem, Pa. Kraus....52–5

Classification of Half-Wave and Full-Wave Nonreversible and Reversible Self-Saturating Circuits, Magnetic Amplifier Circuits—A. McMurtrie....739–51

Closed Circuit Educational Television, A Transmission Design for. Wall....340–6

Vol.
Pt. 1
1959

Closed-Circuit Television in Education, A Design for Using. Almstead........................439–44
Cocentric Annular-Plate Capacitors, Subarea Determination of the Capacitance of. Reitan, Higgins..1002–05
Code Repeater, A Transistorized Pulse. Partridge..826–30
Code Teletypewriter Transmission, An Error-Detection System for 5-Unit-. Barry, Whitman......916–21
(Committee Report) Proposed Standard Test Codes for Magnetic Amplifiers. (59–177).............453–6
(Committee Report) Recommended Symbols for Magnetic Amplifier Papers—A Report. (59–173).................................519–20; disc. 520

Duplexer for Millimeter Waves, A Circular Polarization. Fellers..........934–7
Dynamic Impedance Matching Circuit as Applied to a Conference Repeater, A New. Grandstaff..751–5

E

Eddy-Current Losses in Solid and Laminated Iron. Agarwal..........169–79; disc. 179
Education, A Design for Using Closed-Circuit Television in. Almstead..........439–44
Educational Television, A Talk-Back System for. Norton, Davidson..........209–14
Educational Television, A Transmission Design for Closed Circuit. Wall..........340–6
Effect of Flux Distribution on Iron Losses, The. Shindler..........1069–74
Effects of Gamma Radiation at 25 C on Silicone Dielectrics. Currin..........297–308
Effects of Operation of Germanium Alloy Junction Transistors Above Rated Conditions. Spradlin..........346–52
Effects of Ultrahigh Temperature on Magnetic Properties of Core Materials. Pasnak, Lundsten..........1033–8; disc. 1038
Efficiency in Fast-Response Magnetic Amplifiers, Volt-Second Transfer. Part II. Pula, Lynn, Ringelman..........8–11
Efficiency of Thermoelectric Generators Utilizing P-Type and N-Type Lead Telluride, Design Parameters for Optimizing the. Fritts.......817–20
83B1 Teletypewriter Selective-Calling System, The. Smith, Votaw, Whitman..........119–24
Electric Analog of Heat Flow in Power Transistors, An. Reese, Grannemann, Durant..........640–3
Electric Field on the Charging of Fine Particles, A Theoretical Analysis of the Effects of an. Murphy, Adler, Penney..........318–26
Electric Systems, Transistor-Magnetic Control Circuits for Aircraft. Pratt..........643–50
(Electrical Insulation) A Study of the Effects of Corona on Polyethylene. McMahon, Maloney, Perkins..........654–62
(Electrical Insulation) A Study of Thermal Deterioration of Kraft Pulps Using a Mass Spectrometer. Saito, Hino..........602–06
(Electrical Insulation) Effects of Gamma Radiation at 25 C on Silicone Dielectrics. Currin......297–308
(Electrical Insulation) Magnet Wire for 600 C Temperature Transformers. Wareham..........66–70
(Electrical Insulation) On the Anomaly in Residual Polarization of $BaTiO_3$ Ceramics. Saito, Yamanaka..........70–6
(Electrical Insulation) Properties of Octafluorocyclobutane, a Dielectric Gas. Blodgett..........63–6
(Electrical Insulation) The Use of D-C Overpotential Testing as a Maintenance Tool in the Industrial Plant. Weddendorf..........729–36
(Electrical Insulation) Thermal Life of Enameled Magnet Wire. (Committee Report)..........91–102
Electrical Insulation, Three Decades of Progress in. Berberich..........237–48
Electrical Protection for Transistorized Equipment. Bodle, Hays..........232–7
Electrode Configuration, Current Distribution in the Cylindrical Source Plane-. Comstock, Williams..........252–6
Electrodynamometer for the Precise Measurement of Voltage, Current, Power, and Energy, The Inductronic. Estoppey..........393–8
Electroluminescent Totaling Display, Remotely Controlled. Lyman, Jones, Leger..........248–52
Electromechanical Impedance: Analogs and Duality. Swift..........81–3
Electronic Network Synthesis of Linear Algebraic Matrix Equations. Horn, Honnell..........1028–32
Electronic Switchboard Employing Time-Division Multiplexing, Transmission Aspects of an. Perkins..........949–53
Electronic Telephone Switching System, Considerations Pertaining to the Design of an. Brightman, Tubinis..........777–86
(Electronics) A Theoretical Analysis of the Effects of an Electric Field on the Charging of Fine Particles. Murphy, Adler, Penney..........318–26
(Electronics) Analysis and Design of a Transistor Linear-Delay Circuit. Nanavati..........577–80
(Electronics) Design of a Vertical Magnetic Recording Head with Large-Scale Models. Smith....357–62
(Electronics) Design of Random-Noise Transformers. Vore..........59–63
(Electronics) Effects of Operation of Germanium Alloy Junction Transistors Above Rated Conditions. Spradlin..........346–52
(Electronics) Factors Leading to the Development of Ceramic Hydrogen Thyratrons. Price, Coolidge..........76–80
(Electronics) Field-Strength Measurements in Parallel-Plate Precipitators. Lagarias..........427–33
(Electronics) High-Voltage Rectifier Transformer Problems. Wilson..........352–7
(Electronics) Life Characteristics of Carbon-Film Resistors after 12,000 Hours of Operation. Braner, Easterday..........201–07
(Electronics) Quality Assurance Program. Hulnick, Harding, Rowinski..........326–35
(Electronics) Relation Between Permanent Magnet Configuration and Performance. Cioffi..........979–81; disc. 981
Element Failures, Delayed Neutron Detection Methods Applied to the Detection and Location of Reactor Fuel. Dewes, Childs..........1065–9
Elimination of Coupling Problems in Multistage Magnetic Amplifiers. McMurray..........858–63
Elliptic Functions, Ripple-Type Time-Delay Networks Using. Kiseda, Ford..........996–1002
Enamel Magnet Wire, The Evaluation of. Saums, Pendleton..........1–4
Enameled Magnet Wire, Thermal Life of. (Committee Report)..........91–102
Engineering Aspects of TASI. Bullington, Fraser..........256–60
Engineering of Personal Radio Signaling Systems, Systems. Strack..........55–9
Engineering Problems, The Use of Automatic Programing Techniques for Solving. Carleton, Chackan, Martin..........596–601; disc. 601
Engineers, A New Approach to Training Telephone. Burnett, Adams..........572–6; disc. 576
Engineers, Industry Schools Its. Waldner..........147–52; disc. 152
Equations, Analysis of Series-Connected Saturable Reactor with Capacitive Loading and Finite Control Resistance by Use of Difference. Bourne, Salihi..........461–71
Equations, Electronic Network Synthesis of Linear Algebraic Matrix. Horn, Honnell.......1028–32
Equations—Matrix Logic IV, Simultaneous Logical. Schubert..........1080–3
Equipment, Electrical Protection for Transistorized. Bodle, Hays..........232–7
Equipment, Pagemaster Receiver and Modulation. Young..........45–52
Equivalent Circuit for Transformers in Which Nonlinear Effects Are Present, An. Lord.....580–5; disc. 586
Error-Detection System for 5-Unit-Code Teletypewriter Transmission, An. Barry, Whitman.......916–21
Errors in 5-Level Punched Tape, Detection of Transmission. Steeneck, Caley..........1005–09
Europe and in Underdeveloped Areas, A Review of Telephone Development in Western. Wallenstein..........15–21; disc. 21
Evaluation of Enamel Magnet Wire, The. Saums, Pendleton..........1–4
Evaluation of Magnetic Amplifier Performance Based on Constant-Voltage Reset Test, Graphical. Nitzan..........691–7; disc. 697
Evaluation of Solderless Wrapped Connections for Central Office Use. Elliott..........185–94
Exchange Cable, Manufacture of Composite Cable Sheath for Telephone. Hughes..........650–4
Experience with Long-Distance Television Fields Used for Retransmission. Braun..........594–6
Experimental Study of Detection in Nonstationary Noise, An. Williams, Thomas..........678–82
Experimental Techniques in Nuclear Reactor Design, Computational and. Witzig, Stuart, Herwig..........155–63
Extensions: Application in a Step-by-Step Central Office Area, Indialing to PBX. Schleinkofer..........549–54

F

Factors Leading to the Development of Ceramic Hydrogen Thyratrons. Price, Coolidge..........76–80
Fast-Response Magnetic Amplifiers, Volt-Second Transfer Efficiency in. Part II. Pula, Lynn, Ringelman..........8–11
Feedback in Magnetic Amplifiers, On the. Finzi, Suozzi:
  Part II. Combined Magnetic and Electric Feedbacks..........136–41
Ferrite-Core Memory, A Small High-Speed Transistor and. Shafer, Toy, Priebe..........763–9
Ferroresonance, Theory of. Salihi...755–62; disc. 762
Field on the Charging of Fine Particles, A Theoretical Analysis of the Effects of an Electric. Murphy, Adler, Penney..........318–26
Field-Strength Measurements in Parallel-Plate Precipitators. Lagarias..........427–33
Fields, Conducting Sphere in Alternating Magnetic. Poritsky..........937–42
Film Resistors after 12,000 Hours of Operation, Life Characteristics of Carbon-. Braner, Easterday..........201–07
Filtering, The Computation of Correlation and Spectral Functions by Orthogonal. Gilbert..........954–9
Filters, Basic Concepts of Multidimensional Space. Kron..........554–61
Fine Particles, A Theoretical Analysis of the Effects of an Electric Field on the Charging of. Murphy, Adler, Penney..........318–26
Finite Control Resistance by Use of Difference Equations, Analysis of Series-Connected Saturable Reactor with Capacitive Loading and. Bourne, Salihi..........461–71
Finite Integral Transforms to Analog Simulations, Application of. Karplus, Stephens..........152–5
5-Level Punched Tape, Detection of Transmission Errors in. Steeneck, Caley..........1005–09
Five-Unit-Code Teletypewriter Transmission, An Error-Detection System for. Barry, Whitman....916–21
Flagstaff-Phoenix TJ Radio System, The. Hidy.821–6
Flow Controller, A Magnetic Amplifier. Darling.373–9
Fluoroscopic Image Intensifiers, Standards for Measurement of Brightness Intensification in. Lusby..........504–05; disc. 506
Flux Distribution on Iron Losses, The Effect of. Schindler..........1069–74
4,000, 6,000, and 11,000 Megacycles, Tests Conducted Over Highly Reflective Terrain at. Oxehufwud..........265–70
Four-Wire Y, A Single-Stator Meter for Two Phases of a. Schwartz..........228–31; disc. 231
Frequencies, Transmission Properties of Polyethylene-Insulated Telephone Cables at Voice and Carrier. Eager, Jachimowicz, Kolodny, Robinson..........618–39; disc. 639
Frequency Modulation Inputs, Network Response to Transient. Bucher..........1017–22
Frequency Power Generator Using Transistors, Ultrasonic. Wei..........1062–5
Frequency Shift Carrier Telegraph System, Design Features of a New. Stephens..........927–34
Fuel Element Failures, Delayed Neutron Detection Methods Applied to the Detection and Location of Reactor. Dewes, Childs..........1065–9
Full-Wave Magnetic Amplifier Control Characteristics Affected by Control-Circuit Resistance, Graphical Analysis of. Murakami, Kikuchi..........526–30
Full-Wave Nonreversible and Reversible Self-Saturating Circuits, Magnetic Amplifier Circuits—A Classification of Half-Wave and. McMurtrie.....739–51
Functional Life Tests of Apparatus as Compared with Insulation Material Tests. Manning..........1107–10; disc. 1110
Functions by Orthogonal Filtering, The Computation of Correlation and Spectral. Gilbert..........954–9
Functions—Matrix Logic V, Symmetric Switching. Schubert..........1083–7
Functions, Ripple-Type Time-Delay Networks Using Elliptic. Kiseda, Ford..........996–1002

G

Gamma Radiation at 25 C on Silicone Dielectrics, Effects of. Currin..........297–308
Gas, Properties of Octafluorocyclobutane, a Dielectric. Blodgett..........63–6
General Form of Some Common Network Theorems, The. Adamson, El-Sobki........991–5; disc. 995
Generalized Computer Procedure for the Design of Optimum Systems, A. Brown:
  Part I..........285–9
  Part II..........289–93
Generator, Transistorized Multifrequency Ringing. Kostelich, Howald..........987–91
Generator Using Transistors, Ultrasonic Frequency Power. Wei..........1062–5
Generators Utilizing P-Type and N-Type Lead Telluride, Design Parameters for Optimizing the Efficiency of Thermoelectric. Fritts..........817–20
Germanium Alloy Junction Transistors Above Rated Conditions, Effects of Operation of. Spradlin..........346–52
Global Public Telephone Service—1958. Donald, Chandler..........811–17
Graphical Analysis of Full-Wave Magnetic Amplifier Control Characteristics Affected by Control-Circuit Resistance. Murakami, Kikuchi..........526–30
Graphical Evaluation of Magnetic Amplifier Performance Based on Constant-Voltage Reset Test. Nitzan..........691–7; disc. 697
Graphical Method in the Design of Multiterminal Switching Circuits, The Numerical-. Scheinman..........515–19
Grid Resistance, Correlation of Measured and Calculated Substation Ground. Kinyon...698–701; disc. 701
Ground Grid Resistance, Correlation of Measured and Calculated Substation. Kinyon.698–701; disc. 701

H

Half-Wave and Full-Wave Nonreversible and Reversible Self-Saturating Circuits, Magnetic Amplifier Circuits—A Classification of. McMurtrie.....739–51
Head with Large-Scale Models, Design of a Vertical Magnetic Recording. Smith..........357–62

Vol.
Pt. 1

Overpotential Testing as a Maintenance Tool in the Industrial Plant, The Use of D-C. Weddendorf..........729–36

P

P-Type and N-Type Lead Telluride, Design Parameters for Optimizing the Efficiency of Thermoelectric Generators Utilizing. Fritts..........817–20
Pacific Great Eastern Railway, Microwave Systems on the. Doble, Raftis..........800–06
Pagemaster Receiver and Modulation Equipment. Young..........45–52
Parallel-Plate Precipitators, Field-Strength Measurements in. Lagarias..........427–33
Parameters Affecting the Heart, A-C Shocks of Varying. Kouwenhoven, Knickerbocker, Chesnut, Milnor, Sass..........163–7; disc. 167
Parameters for Optimizing the Efficiency of Thermoelectric Generators Utilizing P-Type and N-Type Lead Telluride, Design. Fritts..........817–20
Particles, A Theoretical Analysis of the Effects of an Electric Field on the Charging of Fine. Murphy, Adler, Penney..........318–26
PBX Extensions: Application in a Step-by-Step Central Office Area, Indialing to. Schleinkofer....549–43
Performance Based on Constant-Voltage Reset Test, Graphical Evaluation of Magnetic Amplifier. Nitzan..........691–7; disc. 697
Performance for Communication and Radar Systems, Marginal Utility and a Criterion of. Schwartz..........117–19
Permanent Magnet Configuration and Performance, Relation Between. Cioffi..........979–81; disc. 981
Personal Radio Signaling Systems, Systems Engineering of. Strack..........55–9
Personal Signaling at Allentown-Bethlehem, Pa., City-Wide. Kraus..........52–5
Phase Velocity of a Shielded Helical Transmission Line, The Characteristic Impedance and. Kirschbaum..........444–50
Phases of a 4-Wire Y, A Single-Stator Meter for Two. Schwartz..........228–31; disc. 231
Phoenix TJ Radio System, The Flagstaff-. Hidy..........821–6
Plane-Electrode Configuration, Current Distribution in the Cylindrical Source. Comstock, Williams..........252–6
Plate Capacitors, Subarea Determination of the Capacitance of Cocentric Annular-. Reitan, Higgins..........1002–05
Polarization Duplexer for Millimeter Waves, A Circular. Fellers..........934–7
Polarization of $BaTiO_3$ Ceramics, On the Anomaly in Residual. Saito, Yamanaka..........70–6
Polyethylene, A Study of the Effects of Corona on. McMahon, Maloney, Perkins..........654–62
Polyethylene-Insulated Multipair Telephone Cable, Design of. Windeler..........736–9
Polyethylene-Insulated Telephone Cables at Voice and Carrier Frequencies, Transmission Properties of. Eager, Jachimowicz, Kolodny, Robinson..........618–39; disc. 639
Polynomial Transforms, Mixed Transcendental and. Smith..........786–95
Polyphase Meter Connections 30 Years After Woodson. Warburton..........398–412; disc. 412
Potentials, Precision Integrator for D-C. Pattee..450–3
Power and Energy, The Inductronic Electrodynamometer for the Precise Measurement of Voltage, Current. Estoppey..........393–8
Power Generator Using Transistors, Ultrasonic Frequency. Wei..........1062–5
Power Inverter, A More Stable 3-Phase Transistor-Core. Jewett, Schmidt..........686–91
Power Law Nonlinearity, Statistical Spectral Output of. Smith..........535–43
Power Plant, A One-Watt Solar. Smith..........530–5
Power Plants, Coolant Instrumentation for Pressurized Water Reactor. Lihota, Hoppa..........131–6
Power Plants, Designs for Large Organic Reactor. Bosworth, Parkins..........964–73
Power Supply for Missile Application, A Magnetic-Amplifier–Silicon-Transistor. Mokrytzki, Stuart..........835–43
Power Systems, Microwaves and Their Use in. Bartlett..........1095–1106; disc. 1106
Power Transistors, An Electric Analog of Heat Flow in. Reese, Grannemann, Durant..........640–3
Precipitators, Field-Strength Measurements in Parallel-Plate. Lagarias..........427–33
Precision Integrator for D-C Potentials. Pattee..450–3
Precision Voltage Dividers, A Method for Calibration of. Pinckney..........182–5
Present Status and Anticipated Progress in the Field of Insulating Materials, The. Callinan..........22–7; disc. 27

Pressurized Reactors, A Rod-Position Indication System for. Floyd, Reuther.......................614-18
Pressurized Water Reactor Power Plants, Coolant Instrumentation for. Lihota, Hoppa.......131-6
Private Telegraph Networks, Synchronous Methods of Operation for. Diamond.......278-83; disc. 283
Problems in Multistage Magnetic Amplifiers, Elimination of Coupling. McMurray............858-63
Problems, The Use of Iterated Laplace Transformations in the Solution of Combined Circuit-Field. Mulligan...................................506-11
Program, Quality Assurance. Hulnick, Harding, Rowinski...................................326-35
Programing Techniques for Solving Engineering Problems, The Use of Automatic. Carleton, Chackan, Martin.......................596-601; disc. 601
Progress in Electrical Insulation, Three Decades of. Berberich...................................237-48
Progress in the Field of Insulating Materials, The Present Status and Anticipated. Callinan.................................22-7; disc. 27
Propagation in Ionized Media, Effects of Nonlinearity on. Cohn...................................942-9
Properties of Modern Teleprinters with Regard to Signal Transmission. Wusteney...........362-7
Properties of Octafluorocyclobutane, a Dielectric Gas. Blodgett...................................63-6
Proposed Standard Test Codes for Magnetic Amplifiers. (Committee Report).......................453-6
Protection for Transistorized Equipment, Electrical. Bodle, Hays...................................232-7
Public Telephone Service—1958, Global. Donald, Chandler...................................811-17
Pulps Using a Mass Spectrometer, A Study of Thermal Deterioration of Kraft. Saito, Hino.......602-06
Pulse Code Repeater, A Transistorized. Partridge...................................826-30
Pulse Modulator, D-C Charged Magnetic. Manteuffel, Cooper...................................843-50
Pulse Transformer, The Optimum Transmission-Line. Young, Schatz, Woodford.......................220-3
Pulse Transformers, Digital Computer Design of. Lego, Greene, Banic...........................217-20
Punched Tape, Detection of Transmission Errors in 5-Level. Steeneck, Caley................1005-09

Q

Quality Assurance Program. Hulnick, Harding, Rowinski...................................326-35

R

Radar Systems, Marginal Utility and a Criterion of Performance for Communication and. Schwartz...................................117-19
Radiation at 25 C on Silicone Dielectrics, Effect on Gamma. Currin.....................297-308
(Radio Communication) A Circular Polarization Duplexer for Millimeter Waves. Fellers.....934-7
(Radio Communication) A New High-Capacity Microwave Relay System. Arnold, Isaac, Mathwich, Privett, Thompson.......................712-22
(Radio Communication) A Transistorized Pulse Code Repeater. Partridge.....................826-30
(Radio Communication) An Approach to the Study of Automatic Target Tracking. Pode.........806-11
(Radio Communication) City-Wide Personal Signaling at Allentown-Bethlehem, Pa. Kraus........52-5
(Radio Communication) Microwave Systems on the Pacific Great Eastern Railway. Doble, Raftis...................................800-06
(Radio Communication) Pagemaster Receiver and Modulation Equipment. Young............45-52
(Radio Communication) Synchronous Methods of Operation for Private Telegraph Networks. Diamond.....................278-83; disc. 283
(Radio Communication) Tests Conducted Over Highly Reflective Terrain at 4,000, 6,000, and 11,000 Megacycles. Oxehufwud.................265-70
(Radio Communication) The Challenge of Universal Mobile Communications. Culbertson......973-9
(Radio Communication) The Design of the Corner-Reflector Antenna. Neff, Tillman.........293-5
Radio Relays and White Noise, CCITT Recommendations for Multichannel. Parry............107-17
Radio Signaling Systems, Systems Engineering of Personal. Strack.........................55-9
Radio System, The Flagstaff-Phoenix TJ. Hidy...................................821-6
Radiotelegraph Communications, Considerations in SSB and ISB Systems for Long-Distance. Lyons...................................921-4
Railway, Microwave Systems on the Pacific Great Eastern. Doble, Raftis..................800-06
Random-Noise Transformers, Design of. Vore...................................59-63
Rapid Determination of Corona Loss From Voltage-Charge Diagrams. Dixon..................207-09
Reactor Core, A Mathematical Model for a Magnetic-Amplifier. Woodson...........872-7; disc. 877
Reactor Design, Computational and Experimental Techniques in Nuclear. Witzig, Stuart, Herwig...................................155-63
Reactor Fuel Element Failures, Delayed Neutron Detection Methods Applied to the Detection and Location of. Dewes, Childs...............1065-9
Reactor Model, Analysis of Magnetic Amplifiers Using a Resistive. Frankenthal..........850-7; disc. 857
Reactor Power Plants, Coolant Instrumentation for Pressurized Water. Lihota, Hoppa.........131-6
Reactor Power Plants, Designs for Large Organic. Bosworth, Parkins.......................964-73
Reactors, A Rod-Position Indication System for Pressurized. Floyd, Reuther...............614-18
Reactors, Two-Step Switching of Saturable. Lovell...................................895-900
Realizability of the Inductance Matrix, Criteria and Tests for. Tokad, Reed...............924-6
Receiver and Modulation Equipment, Pagemaster. Young...................................45-52
Recommendations for Multichannel Radio Relays and White Noise, CCITT. Parry...........107-17
Recommended Symbols for Magnetic Amplifier Papers—A Report. (Committee Report)...................................519-20; disc. 520
Recording Head with Large-Scale Models, Design of a Vertical Magnetic. Smith..............357-62
Rectifier, A Silicon-Controlled. Bisson, Dyer:
  Part I. Characteristics and Ratings.........102-06
Rectifier Transformer Problems, High-Voltage. Wilson...................................352-7
Recurrence Relations in the Solution of a Certain Class of Nonlinear Systems. Wolf........830-4; disc. 834
Reflector Antenna, The Design of the Corner-. Neff, Tillman...................................293-5
Regulation in Magnetic Transistor-Amplifiers, Self-. Hardies, Van Allen..................905-09
Regulators with Self-Balancing Magnetic Amplifiers, Automatic. Geyger.....................433-8
Relation Between Permanent Magnet Configuration and Performance. Cioffi...........979-81; disc. 981
Relations in the Solution of a Certain Class of Nonlinear Systems, Recurrence. Wolf...................................830-4; disc. 834
Relay System, A New High-Capacity Microwave. Arnold, Isaac, Mathwich, Privett, Thompson...................................712-22
Relays and White Noise, CCITT Recommendations for Multichannel Radio. Parry.............107-17
Remotely Controlled Electroluminescent Totaling Display. Lyman, Jones, Leger...........248-52
Repeater, A New Dynamic Impedance Matching Circuit as Applied to a Conference. Grandstaff...................................751-5
Repeater, A New Transistorized Negative-Impedance Telephone. Dimmer, Roback..............673-8
Repeater, A Transistorized Pulse Code. Partridge...................................826-30
Repeater Employing Transistors, A Miniaturized Negative-Impedance Voice. Howell........11-15
Reperforator-Teletypewriter TT-195()/FG. Frick...................................369-73
Reset Test, Graphical Evaluation of Magnetic Amplifier Performance Based on Constant-Voltage. Nitzan...................................691-7; disc. 697
Residual Polarization of $BaTiO_3$ Ceramics, On the Anomaly in. Saito, Yamanaka.............70-6
Resistance by Use of Difference Equations, Analysis of Series-Connected Saturable Reactor with Capacitive Loading and Finite Control. Bourne, Salihi...................................461-71
Resistance, Correlation of Measured and Calculated Substation Ground Grid. Kinyon...................................698-701; disc. 701
Resistance of Solid Magnetic Wires, The A-C. Gohar...................................912-16
Resistive Reactor Model, Analysis of Magnetic Amplifiers Using a. Frankenthal......850-7; disc. 857
Resistors after 12,000 Hours of Operation, Life Characteristics of Carbon-Film. Braner, Easterday...................................201-07
Response of Tapered Transmission Lines, The Transient. Young, Schatz, Woodford........223-8; disc. 228
Response, Some Practical Methods of Obtaining Time of. Van Allen, Covert, Wilson...........900-05
Response to Transient Frequency Modulation Inputs, Network. Bucher.....................1017-22
Retransmission, Experience with Long-Distance Television Fields Used for. Braun...........594-6
Reversible Self-Saturating Circuits, Magnetic Amplifier Circuits—A Classification of Half-Wave and Full-Wave Nonreversible and. McMurtrie.....739-51
Review of Telephone Development in Western Europe and in Underdeveloped Areas, A. Wallenstein...................................15-21; disc. 21
Ringing Generator, Transistorized Multifrequency. Kostelich, Howald.......................987-91
Ripple-Type Time-Delay Networks Using Elliptic Functions. Kiseda, Ford................996-1002
Rod-Position Indication System for Pressurized Reactors, A. Floyd, Reuther...............614-18

S

(Safety) A Comparison of Mouth-to-Mouth and Manual Artificial Respiration Techniques. Gordon, Frye...................................86-91
(Safety) A-C Shocks of Varying Parameters Affecting the Heart. Kouwenhoven, Knickerbocker, Chesnut, Milnor, Sass.................163-7; disc. 167

Time of Response, Some Practical Methods of Obtaining. Van Allen, Covert, Wilson..........900–05
TJ Radio System, The Flagstaff-Phoenix. Hidy..... 821–6
Totaling Display, Remotely Controlled Electroluminescent. Lyman, Jones, Leger..........248–52
Tracking, An Approach to the Study of Automatic Target. Pode..........806–11
Traffic, Subdivision of Telephone. Molnar......28–45
Training Telephone Engineers, A New Approach to. Burnett, Adams..........572–6; disc. 576
Transcendental and Polynomial Transforms, Mixed. Smith..........786–95

Vol.
Pt. 1
1959

Transfer Efficiency in Fast-Response Magnetic Amplifiers, Volt-Second. Part II. Pula, Lynn, Ringelman........8-11
Transformations in the Solution of Combined Circuit-Field Problems, The Use of Iterated Laplace. Mulligan........506-11
Transformer Problems, High-Voltage Rectifier. Wilson........352-7
Transformer, The Optimum Transmission-Line Pulse. Young, Schatz, Woodford........220-3
Transformers, Design of Random-Noise. Vore..59-63
Transformers, Digital Computer Design of Pulse. Lego, Greene, Banic........217-20
Transformers in Which Nonlinear Effects Are Present, An Equivalent Circuit for. Lord. 580-5; disc. 586
Transformers, Magnet Wire for 600 C Temperature. Wareham........66-70
Transforms, Mixed Transcendental and Polynomial. Smith........786-95
Transforms to Analog Simulations, Application of Finite Integral. Karplus, Stephens........152-5
Transient Frequency Modulation Inputs, Network Response to. Bucher........1017-22
Transient Response of Tapered Transmission Lines, The. Young, Schatz, Woodford........223-8; disc. 228
Transients in the Series-Connected Saturable Reactor With High-Impedance Control Source. Goldstein........521-6
Transistor-Amplifiers, Self-Regulation in Magnetic. Hardies, Van Allen........905-09
Transistor and Ferrite-Core Memory, A Small High-Speed. Shafer, Toy, Priebe........763-9
Transistor-Core Power Inverter, A More Stable 3-Phase. Jewett, Schmidt........686-91
Transistor Linear-Delay Circuit, Analysis and Design of a. Nanavati........577-80
Transistor-Magnetic Control Circuits for Aircraft Electric Systems. Pratt........643-50
Transistor Magnetic-Core Memories, All-. Goda, Johnston, Markowitz, Rosenberg, Staurt-Williams........666-73
Transistor Power Supply for Missile Application, A Magnetic-Amplifier–Silicon-. Mokrytzki, Stuart........835-43
Transistorized Equipment, Electrical Protection for. Bodle, Hays........232-7
Transistorized Multifrequency Ringing Generator. Kostelich, Howald........987-91
Transistorized Negative-Impedance Telephone Repeater, A New. Dimmer, Roback........673-8
Transistorized Pulse Code Repeater, A. Partridge........826-30
Transistorized 20-Channel Carrier Telegraph Terminal, A. Grybowski, Vieth........260-5
Transistors, A Miniaturized Negative-Impedance Voice Repeater Employing. Howell........11-15
Transistors Above Rated Conditions, Effects of Operation of Germanium Alloy Junction. Spradlin........346-52
Transistors, An Electric Analog of Heat Flow in Power. Reese, Grannemann, Durant........640-3
Transistors, Ultrasonic Frequency Power Generator Using. Wei........1062-5
Transmission, An Error-Detection System for 5-Unit-Code Teletypewriter. Barry, Whitman........916-21
Transmission, Application of Telegraph Techniques in Data. Boggs, Boughtwood........336-40
Transmission Aspects of an Electronic Switchboard Employing Time-Division Multiplexing. Perkins........949-53
Transmission Design for Closed Circuit Educational Television, A. Wall........340-6
Transmission Errors in 5-Level Punched Tape, Detection of. Steeneck, Caley........1005-09
ransmission-Line Pulse Transformer, The Optimum. Young, Schatz, Woodford........220-3
Transmission Line, The Characteristic Impedance and and Phase Velocity of a Shielded Helical. Kirschbaum........444-50
Transmission Lines, The Transient Response of Tapered. Young, Schatz, Woodford........223-8; disc. 228
Transmission, Properties of Modern Teleprinters with Regard to Signal. Wusteney........362-7
Transmission Properties of Polyethylene-Insulated Telephone Cables at Voice and Carrier Frequencies. Eager, Jachimowicz, Kolodny, Robinson................618-39; disc. 639
Transposition System for Carrier Systems Up to 156 Kc, A. Kirkland........612-14
12,000 Hours of Operation, Life Characteristics of Carbon-Film Resistors after. Braner, Easterday........201-07
20-Channel Carrier Telegraph Terminal, A Transistorized. Grybowski, Vieth........260-5
25 C on Silicone Dielectrics, Effects of Gamma Radiation at. Currin........297-308
250-Degree Instruments, Taut-Band Suspensions for. Thomander, MacIndoe........379-83; disc. 383
Two-Oscillator Scan Stability. Joseph........1022-8
Two Phases of a 4-Wire Y, A Single-Stator Meter for. Schwartz........228-31; disc. 231
Two-Step Switching of Saturable Reactors. Lovell........895-900

U

Ultrahigh Temperature on Magnetic Properties of Core Materials, Effects of. Pasnak, Lundstern................1033-8; disc. 1038
Ultrasonic Frequency Power Generator Using Transistors. Wei........1062-5
Universal Mobile Communications, The Challenge of. Culbertson........973-9
Use of Automatic Programing Techniques for Solving Engineering Problems, The. Carleton, Chackan, Martin........596-601; disc. 601
Use of D-C Overpotential Testing as a Maintenance Tool in the Industrial Plant, The. Weddendorf. 729-36
Use of High-Speed Digital Computers to Study Performance of Complex Switching Networks Incorporating Time Delays. Chang, George........982-7
Use of Iterated Laplace Transformations in the Solution of Combined Circuit-Field Problems, The. Mulligan........506-11
Utility and a Criterion of Performance for Communication and Radar Systems, Marginal. Schwartz........117-19

V

Velocity of a Shielded Helical Transmission Line, The Characteristic Impedance and Phase. Kirschbaum........444-50
Vertical Magnetic Recording Head with Large-Scale Models, Design of a. Smith........357-62
Voice Repeater Employing Transistors, A Miniaturized Negative-Impedance. Howell........11-15
Volt-Ampere Converter for Current and Voltage Measurements, A Wide Range. Hermach, Williams........384-8
Volt-Second Transfer Efficiency in Fast-Response Magnetic Amplifiers. Part II. Pula, Lynn, Ringelman........8-11
Voltage-Charge Diagrams, Rapid Determination of Corona Loss From. Dixon........207-09
Voltage, Current, Power, and Energy, The Inductronic Electrodynamometer for the Precise Measurement of. Estoppey........393-8
Voltage Dividers, A Method for Calibration of Precision. Pinckney........182-5
Voltage Measurements, A Wide Range Volt-Ampere Converter for Current and. Hermach, Williams........384-8
Voltage Reset Test, Graphical Evaluation of Magnetic Amplifier Performance Based on Constant-. Nitzan........691-7; disc. 697

W

Water Reactor Power Plants, Coolant Instrumentation for Pressurized. Lihota, Hoppa........131-6
Waves, A Circular Polarization Duplexer for Millimeter. Fellers........934-7
Weather Information Distribution System, A High-Volume High-Speed. Schwenzfeger........722-8
Western Europe and in Underdeveloped Areas, A Review of Telepnone Development in. Wallenstein........15-21; disc. 21
White Noise, CCITT Recommendations for Multichannel Radio Relays and. Parry........107-17
Wide Range Volt-Ampere Converter for Current and Voltage Measurements, A. Hermach, Williams........384-8
Winding Capacitances in Magnetic Amplifiers, The. Johansen........702-07
(Wire Communications) A Miniaturized Negative-Impedance Voice Repeater Employing Transistors. Howell........11-15
(Wire Communications) A New Approach to Training Telephone Engineers. Burnett, Adams................572-6; disc. 576
(Wire Communications) A New Transistorized Negative Impedance Telephone Repeater. Dimmer, Roback........673-8
(Wire Communications) A Review of Telephone Development in Western Europe and in Underdeveloped Areas. Wallenstein........15-21; disc. 21
(Wire Communications) A Transposition System for Carrier Systems Up to 156 Kc. Kirkland..612-14
(Wire Communications) Design of Polyethylene-Insulated Multipair Telephone Cable. Windeler. 736-9
(Wire Communications) Electrical Protection for Transistorized Equipment. Bodle, Hays....232-7
(Wire Communications) Engineering Aspects of TASI. Bullington, Fraser........256-60
(Wire Communications) Industry Schools Its Engineers. Waldner........147-52; disc. 152
(Wire Communications) Manufacture of Composite Cable Sheath for Telephone Exchange Cable. Hughes........650-4
(Wire Communications) Synthesis of Cable Simulation Networks. DeMonte........682-6
(Wire Communications) The Design and Manufacture of Direct Burial Wire. Robb, Roberts................662-6; disc. 666
(Wire Communications) The K24A Syncroplex Telephone Carrier System. Coetsee, Curtis, Halina................1044-54; disc. 1054
(Wire Communications) Transistorized Multifrequency Ringing Generator. Kostelich, Howald...987-91
(Wire Communications) Transmission Properties of Polyethylene-Insulated Telephone Cables at Voice Carrier Frequencies. Eager, Jachimowicz, Kolodny, Robinson........618-39; disc. 639
Wire for 600 C Temperature Transformers, Magnet. Wareham........66-70
Wire, The Evaluation of Enamel Magnet. Saums, Pendleton........1-4
Wire, Thermal Life of Enameled Magnet. (Committee Report)........91-102
Wires, The A-C Resistance of Solid Magnetic. Gohar........912-16
Woodson, Polyphase Meter Connections 30 Years After. Warburton........398-412; disc. 412
Wrapped Connection for Central Office Use, Evaluation of Solderless. Elliott........185-94

The Evaluation of Enamel Magnet Wire

H. L. SAUMS
MEMBER AIEE

W. W. PENDLETON
MEMBER AIEE

Synopsis: This paper is a discussion of the need to broaden the base of test procedures relating to enameled magnet wires. At present, the AIEE Publication no. 57, revised in 1959, establishes a method for determining the relative life of enameled wires as a function of thermal stability.[1] Also available to air evaluation are the AIEE test procedures 65, 510, and 511.[2] These are intended for evaluation of systems of which magnet wire insulations are an integral part. Experience is showing the desirability of providing acceptable test procedures for determining the relative life and the practicability or suitability of magnet wires as functions of other characteristics. Of importance, in this respect, are: 1. compatibility of the wire enamels with other substances, both of insulating function and environmental in nature, which are present in a complete electrical system, 2. thermoplastic flow properties, 3. heat shock characteristics, 4. change of reaction rate of aging properties with increase in temperature, 5. heat softening after extended aging, 6. retention of flexibility after aging, and 7. winding problems reflected in abrasion resistance, flexibility, reaction to rapid elongation, etc.

IT IS NOT the purpose of this paper to discredit or otherwise replace the present AIEE test procedures. They represent excellent beginning tests to evaluate the thermal stability of magnet wire. What is intended is a means for going beyond these tests in a complete evaluation of a wire for practical use at the indicated temperature level. It can be shown, for instance, that some testing done by the suggested methods can lead to erroneous extrapolation of the life-temperature curves unless supporting data are available. It is the purpose of the paper to bring out the important supporting evidence needed to insure the correct thermal rating of a magnet wire enamel. The normal standard tests made by the magnet wire producers for many years are important. However, recent advances in thermal stability of organic materials make important some additional test procedures such as varnish compatibility tests, moisture tests in sealed tubes, effects of other insulating components on wire enamels, and environmental tests. Most of these tests were unnecessary at class 105 C (degrees centigrade) (A) temperatures but are all important at class 130 C (B) and above. The reason for this change of emphasis is that chemical reactions are increased at a rapid rate with increased temperature. For example, the effects of active contaminants can be increased by a factor of 30 or more in raising the temperature from 105 to 155 C. Since aging is often carried out at greatly accelerated temperatures, the possibility of reactions taking place in short periods of time is great. Such "side reactions" can alter the thermal stability picture for high-stability materials to a much greater extent than for standard class 105 C materials.

The effects of incompatibility between magnet wire enamel and varnish are magnified at the higher temperatures. Thus, Formvar can be treated with a number of varnishes, some of which are not compatible with it, but there is no marked lowering of thermal stability while the same varnishes on a polyester enamel can result in a wide variety of life-temperature characteristics. If the postulation is correct that cracks are formed by nonuniform shrinkage of unlike films, the higher temperatures would accentuate this action. Softening or embrittlement of enamel and evolution of active or passive by-products, may also be active in the aging process.

Moisture problems, especially in enclosed systems, become important at the class 130 and class 155 C levels.

The environment problem includes the uses of gases other than air, liquids such as oil, askarel, and others, and solid potting compounds and resins such as epoxy, polyesters, and modifications. The thermal stability of a magnet wire enamel may be greatly affected by the test medium. While it is agreed that air is the most used medium for presently designed apparatus, there is a tendency toward the use of inert and electronegative gases in large transformers, potting compounds, and high temperature liquid insulants for smaller units, and freons and other liquids or gases for hermetically sealed rotating equipment. It is considered important that magnet wire enamels and other insulating components be given (for the benefit of the users) a series of thermal classifications based on environment, type of supporting insulations, and type of electric device. Furthermore, it is necessary to have a list of compatible and noncompatible components to be used or avoided when use is made of the magnet wire enamel being evaluated.

Definition of Magnet Wire

Before attempting to discuss in detail the ramifications of the subject, it seems of value to define magnet wire in order that its properties may be best used and to forestall any misuse derived from misconceptions of its purpose in electric devices.

Magnet wire, as conceived by Joseph Henry more than 125 years ago, is defined as a continuous insulated length of conducting metal capable of being wound either by form or in random manner on a supporting arbor or in or on an insulated ferromagnetic armature of core for the express purpose, in the completed device, of carrying electric current for the establishment of an electric field associated with the magnetic circuit upon which it is wound. The insulation on magnet wire is present only to separate individual turns so that only one wire path is open to the passage of electric current. Magnet wire must have associated insulation to withstand applied voltage to ground or between phases, to cement adjacent turns in a consolidated mass, and to protect against external damage and contamination; see Fig. 1.

Magnet wire insulation is at the major source of heat, the I^2R (current resistance) loss in the conductor. In a given device, it is therefore the most likely insulating component to be subjected to

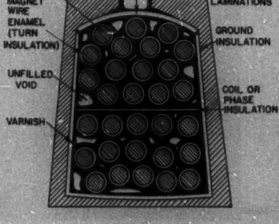

Fig. 1. Function of magnet wire enamel

Paper 58-401, recommended by the AIEE Electrical Insulation Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, N. Y., June 22–27, 1958. Manuscript submitted February 17, 1958; made available for printing September 12, 1958.

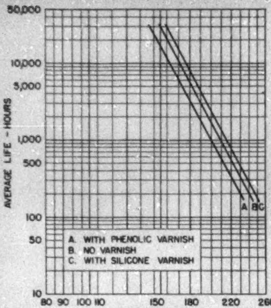

Fig. 2. Effects of varnish type on thermal stability of high-temperature enamel

the "hottest" spot (highest temperature). It is also in a position least able to be cooled and is dependent on associated insulation for conducting its heat to the cooling medium. If the latter is air or a gas, it is important that varnishes or compounds deeply penetrate the windings so that high thermal conductivity materials are present to remove the heat from the wire. If the coolant is a liquid, it is important that all air and moisture be removed before impregnation.

The best advantages of enameled wire in comparison with fiber-insulated types are found in high space factor, excellent flexibility, smooth exterior, high dielectric strength, and often moisture resistance. Even greater space factors are realized when square and rectangular film-insulated wires are used in place of round wire.

The high dielectric strength of magnet wire enamels has tempted some users to eliminate some portions of supporting insulation in the quest for economy of design. This is considered unwise for the following reasons: 1. Magnet wire, unless in very thick grades (triple or quadruple), may have one unavoidable discontinuity of microscopic size in each 10 feet of wire length. 2. Unavoidable winding damage may occur. 3. Expansion and contraction in a finished device in the field may wear the wire in contact with unprotected iron slots. 4. Surge voltages from switching, etc., may exceed the dielectric strength of the wire. 5. Contamination may ground a winding which is separated only by the wire enamel.

The moisture resistance advantage of film insulation over fiber insulation is sometimes of fleeting importance. Some film insulations, possessing moisture resistance at room temperature, are susceptable to attack by moisture under certain high-temperature conditions.

In the magnet wire definition are the words "capable of being wound." It is important that the basic physical and thermal tests be made in any evaluation of thermal stability of an enameled wire. Such properties as flexibility, abrasion resistance, adherence, heat shock, thermoplastic flow, and conductor hardness are important in respect to arriving at specimens which can be properly tested. A serious deficiency in any one property will give test results which are noninterpretable.

Compatibility Problems

At the top of the list of auxiliary data needed beyond the AIEE test data are the problems associated with compatibility. The word "compatibility" has been used to describe the effects of the combination of enamel and varnish and other insulation members when subjected to aging conditions. It has also been used to describe the effects of environmental conditions and presence of contaminants. In other words, compatibility is used to describe how a magnet wire enamel "gets along" with its neighbors, whether they are insulating or contaminating.

The foremost compatibility problem facing the user of the new higher thermal stability enamels is the matching of varnishes or impregnating compounds with the enamels. It is known that varnishes can add to, subtract from, or leave unchanged the thermal stability of a wire enamel; see Fig. 2. If the varnish does not reduce the thermal stability of the enamel it is considered compatible. A complete picture of the thermal stability of a wire enamel would give life-temperature curves for unvarnished specimens; for varnished specimens in at least six categories: silicone, polyester, epoxy, Sylkyd, phenolic, and alkyd; and for motorette or motor tests using the same varnishes and with possible variations in slot insulation and phase insulation. The AIEE twist test has been designed as a screening test, since it is simpler to carry out than the motorette and motor tests.[1] It was envisioned that any varnish incompatibility found in this simple test method would save further testing in the more complex tests. There are, however, incompatibilities which are brought out only by the system tests, and thus it is important that these tests be run in addition to the twist tests for an accurate picture of thermal stability. An important additional test method for compatibility of wire enamels with other insulating components and in the presence of contaminants and environmental components is the sealed tube test; see Fig.

Vol.
Pt. 1
1959

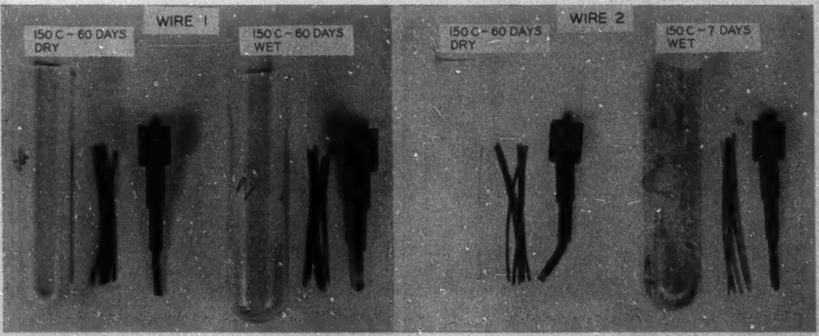

Fig. 3. Sealed tube test method of determining compatibility

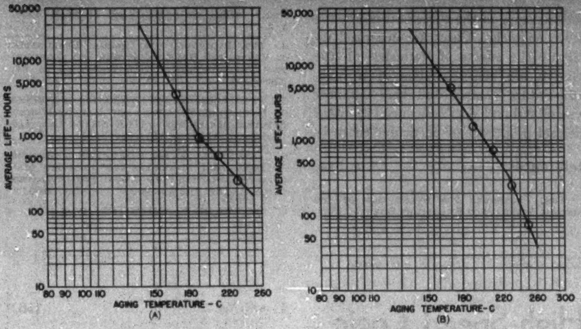

A—Decreased reaction rate

B—Increased reaction rate

Fig. 4. Reaction rates at high temperature

3. Wires are wound on a step mandrel whose diameters are one, three, five, and ten times that of the wire. These specimens are removed from the mandrel and placed (either varnished or unvarnished) in glass tubes sealed at the lower end. Into each tube are placed pieces of insulation such as would be used for supporting insulation in an electric machine. The tube is narrowed to a thin neck and its atmosphere adjusted to give dry, moist, or wet conditions in air or in other gases, and it is finally sealed by torch. The tubes are placed in ovens at various temperatures and observed for cracking and discoloration as aging progresses. Any injurious by-products of aging from other components are concentrated in this test and the results represent the worst conditions. They are, however, indicative of possible weaknesses under extreme conditions. Tests of this kind are shown for two different wire types in Fig. 3. Type *1* wire resists the effects of moisture up to 60 days at 150 C. Some discoloration is beginning to show on the straight lengths of wire and on the *1X* mandrel wrap. Type *2*, however, is rapidly attacked so that in 7 days the enamel is partially removed from the wire. Even in the dry condition, where air was used to break a vacuum drawn on the tube prior to sealing the system, type *2* wire shows some hydrolysis effects, presumably from moisture which was not entirely removed by evacuation. Such a wire would be expected to give some difficulties where moisture is not continually being removed from a system by open-air cooling. A similar statement may be made concerning chlorinated supporting insulations where the possibility of HCl as a gas or as an acid may be liberated and concentrated by the lack of free-air cooling. In the latter case, however, even in open apparatus, such members as polyvinyl chloride and neoprene may be objectionable with type *2* enamels. Compatibility of magnet wire enamels with insulating liquids is also a problem of making use of the higher temperature enamels in liquid-filled class 130 C devices. Again, sealed tube tests provide a convenient method for observing the effects of liquid on enamel and enamel on liquid at elevated temperatures and controlled atmospheres.

Effects of Thermal Characteristics of Enamel on Life-Temperature Curves

The assumption is made in the AIEE test procedures that there will be a single reaction rate from the highest testing temperature to the extrapolated use point of the wire. It is experimentally true that this condition holds for many of the materials studied. However, there are some enamels which do not follow a single reaction rate. Following the life-temperature curve from 10,000 hours to lesser periods of time, there may be a point (tentatively identified with the thermoplastic flow point) where there is a mild or a pronounced transition to a second reaction rate which may be greater or less than the longer life reaction rate (at lower temperatures). Figs. 4(A) and 4(B) illustrate these conditions. It is obvious that any reliable extrapolation of these curves to lower temperatures requires three or four points which are well removed from the knee of the curves.

A second phenomenon has been uncovered for still another type of enamel; the apparent discontinuous life-temperature curve, as shown in Fig. 5. At a point near the thermoplastic flow point of the enamel, these characteristics change in a radical manner, so that high-temperature tests extrapolate to a much lower life expectancy than the lower temperature tests. Such an enamel would give excellent service only where no excessive overloads were encountered. These test results all indicate that high temperatures transform the enamel sufficiently to alter its aging rate. It is further indicative of the effects of thermoplastic flow point on the shape of the life-temperature curves. One other possibility is that tests at temperatures exceeding a certain level produce a heat shock condition in the test specimens even though the bending is mild. It is thus important that a wire enamel have sufficient heat shock resistance to allow accelerated aging in the AIEE test procedures.

A recent test program on a material with a rather low thermoplastic flow point, but with a thermal life expectancy of class 180 C levels shows that accelerated aging is not possible due to premature cut-through of the insulation. Such insulation would always be vulnerable to overload heating even though the basic material may be unaffected, chemically, at the time of the overheating.

Summary

That a completely interpretable and useful analysis might be made of a wire enamel, this paper emphasizes the need to broaden the base of testing enameled magnet wire with AIEE test procedures, and the need of compatibility tests involving sealed tubes and other thermal and physical tests on the wire.

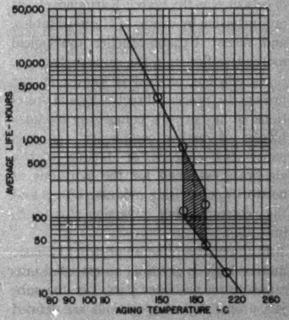

Fig. 5. Discontinuous reaction rate characteristic

It is found that the use of organic enamels at classes 130 C and 155 C necessitates a much closer look at compatibility, thermoplastic flow, heat shock, moisture resistance, and environmental effects than has been given to class 105 C enamels in the past.

The matching of varnish and enamel, the elimination of chemically contaminating supporting insulation, and the proper choice of design and media are important steps in the successful use of the newer enamels. Cases are discussed involving the effects of varnishes on the relative life characteristics of a high-temperature enamel and the nonlinear type of stability data influenced by other thermal properties of particular enamels.

Matrix Synthesis of High-Speed Logic

E. J. SCHUBERT
ASSOCIATE MEMBER AIEE

Synopsis: The object of this paper is to describe a method for synthesizing function matrices from logical conditions and for detecting redundancy prior to designing the network. Accordingly the paper discusses the following: 1. the definition of function matrices and logical operations; 2. the expansion of logical functions in view of additional logical conditions imposed by another variable; and 3. minimization routines.

CONVENTIONAL Boolean algebra and set-theory as applied for the analysis and minimization of logical networks are limited to a few variables. In electronic equipment with diode and transistor circuitry the number of variables increases rapidly. Boolean equations for these large networks become too cumbersome and the method breaks down eventually due to inefficiency in dealing with the multitude of possible permutations. Graphical representations of sets such as the Veitch-Karnaugh chart, minimization by means of Harvard tables, and recent Urbano-Mueller topological methods suffer from the same restriction.

No efficient method is known at the present to process directly logical functions of a network comprising modular blocks of higher complexity. In this paper the concept of binary matrix algebra is extended for the synthesis of networks comprising modular blocks and the corresponding inversion for minimization.

In the next section an abstract of basic matrix logic is given as an essential prerequisite for the later part. In the subject proper logical operations are defined by a matrix operator $[h]$ with reference to the relation between two variables. By substituting for one of the variables a complete function matrix, a method for network synthesis is derived, called the "expansion theorem." The inverted matrix routine is applicable for the minimization of networks by multiplying the function matrix with a redundancy matrix. The product directly comprises the redundant terms and the irrelevant variables.

Function Matrices

The behavior of a logical network is described explicitly in a truth table by referring to any possible combination of the p independent variables. The set of p variables may assume 2^p states in certain AND or OR conditions called minterm or maxterm, respectively. A minterm N_i is any one of the 2^p distinct AND conditions of all p variables in which these variables are or are not complemented in either of the two possible ways. The suffix of N_i is the octal equivalent of the binary number formed by writing ZERO for each complemented variable and ONE for each uncomplemented variable, in the order of their appearance. Any function Y of p variables can be expressed as a polynomial of all minterms with appropriate coefficients F_i.

$$Y = F_0N_0 + F_1N_1 + \dots + F_qN_q \tag{1A}$$

wherein the coefficients F_i have the values of ONE or ZERO according to the appropriate column for the function Y in the composite truth table.

Using the Einstein convention for the matrices involved, i denotes the dummy index between 0 and $2^p - 1$; z is the fixed index. Capital letters designate the individual terms of the corresponding matrices in index notations.

$$Y_z = F_{zi}N_i \tag{1B}$$

OR Operation. The sum of minterms is by definition an OR operation. Because functions are expressed as sums of minterms, any sum of functions Y_z again will be a sum of minterms.

$$Z = Y_{1i} + Y_{2i} = (F_i + G_i)N_i$$

AND Operation. To obtain an output Z from an AND gate implies that both the Y_1 and Y_2 inputs into the gate are ONE. The state of the output depends on the coefficients of the function matrices, F_i and G_i. Z can be ONE only if the coefficients in both matrices with identical suffix are ONE. All other minterms must be inhibited.

$$Z = Y_{1i}Y_{2i} = (F_iG_i)N_i$$

Negation. This operation implies that each F_{zi} term must be substituted by its complement.

$$F_{zi} + F_{zi}' = 1 \qquad '\dots\text{NOT}$$

$$F_{zi}' = 1 - F_{zi}$$

It is understood that the minterm matrix is 1-dimensional in any case comprising only one row or column, and identical for any operation performed in a particular system. The function matrix may comprise up to 2^{2^p} rows, but in practice only those rows describing utilized outputs are considered.

$$Y_z' = (1 - F_{zi})N_i$$

Certain rules are pertinent to establish the function matrix properly, particularly for those input conditions where not all variables are involved.[1]

Table I. Logical Operations

Boolean Notation	Matrix Operator [h]				Operation
	H_0	H_1	H_2	H_3	
$Y_0=0$	0	0	0	0	OFF
$Y_1=X_1'X_2'$	1	0	0	0	NOR
$Y_2=X_1X_2$	0	1	0	0	
$Y_3=X_2'$	1	1	0	0	ONLY X_2'
$Y_4=X_1'X_2$	0	0	1	0	
$Y_5=X_1'$	1	0	1	0	ONLY X_1'
$Y_6=X_2'X_1+X_2X_1'$	0	1	1	0	EITHER 3)
$Y_7=X_1'+X_2'$	1	1	1	0	NOT-AND (Sheffer's Stroke)
$Y_{10}=X_1X_2$	0	0	0	1	AND
$Y_{11}=X_1X_2+X_1'X_2$	1	0	0	1	ONLY IF 3)
$Y_{12}=X_1$	0	1	0	1	ONLY X_1
$Y_{13}=X_1+X_2'$	1	1	0	1	
$Y_{14}=X_2$	0	0	1	1	ONLY X_2
$Y_{15}=X_2+X_1'$	1	0	1	1	IF THEN 3)
$Y_{16}=X_1+X_2$	0	1	1	1	OR
$Y_{17}=1$	1	1	1	1	ON

Logical Operations

Functions of two variables are most suitable for representing logical operations.[2] A table of these basic operations may be derived as follows.

Coefficients H_i describe the operation $[h]$ with respect to the individual minterms formed by X_1 and X_2 respectively, according to equations 1(A) and (B), and are listed in Table I. The functions Y_0 OFF and Y_{17}ON are trivial. Four functions, Y_3, Y_5, Y_{12}, and Y_{14}, are truly functions of one of the two variables only. Y_{10} is the basic AND function, Y_{16} is the "inclusive OR" function to be distinguished from Y_6, the "exclusive OR" or "EITHER" function. Several other functions have been defined elsewhere but are not conventional.[3] Recently the NOR function Y_1 has been widely used in RCTL (resistor-coupled-transistor logic) and certain magnetic networks.[4,5]

Completely different is the NOT-AND function Y_7, which has been introduced because of its significance in certain types of redundancy. It is identical with the Sheffer's stroke function.

Expansion Theorem

Expansion of a logical function V of a set of p variables, $U_1 \ldots U_p$, is the process of introducing an additional variable U under the conditions specified by the operator H.

$$V=f(U_1, U_2 \ldots U_{p-1}, U_p) \tag{2A}$$

$$V=F_iN_i \qquad i=0\ldots(2^p-1) \tag{2B}$$

$$W=f(H, V, U) \tag{2C}$$

This resulting output W is a certain function, g, of the enlarged set of $p+1$ variables.

$$W=g(V_1, V_2 \ldots V_p, V_{p+1}) \tag{2D}$$

$$W=G_iN_i+G_jN_j \quad j=2^p\ldots(2^{p+1}-1) \tag{2E}$$

To derive the function matrix $[g]$ directly from $[f]$ and $[h]$, is the concept of the expansion theorem for computing the coefficients $G_{i,j}$ according to the matrix equation

$$\begin{bmatrix} G_i \\ G_j \end{bmatrix} = \begin{bmatrix} H_0 & H_1 \\ H_2 & H_3 \end{bmatrix} \begin{bmatrix} F_i' \\ F_i \end{bmatrix} \tag{3}$$

To prove the relation 3 requires only to develop 2(E). The variables, U and V, may assume four states only.

$$W=H_0U'V'+H_1U'V+H_2UV'+H_3UV \tag{4A}$$

$$W=U'(H_0V'+H_1V)+U(H_2V'+H_3V) \tag{4B}$$

$$W=U'(H_0F_i'+H_1F_i)N_i+U(H_2\times F_i'+H_3F_i)N_i \tag{4C}$$

$$N_i=U'N_i$$

$$N_j=UN_i \tag{4D}$$

$$G_i=H_0F_i'+H_1F_i$$

$$G_j=H_2F_i'+H_3F_i \tag{4E}$$

The paired equations 4(C) may be rewritten as the single matrix relation 3.

Revised Minimization Concept

Overemphasis of minimization techniques appears to be a tradition rather than an actual economical goal in the design of high-speed logic. For data processing in the megacycle range, proper matching, minimum delay, and fast rise time become more important in order to reduce the number of pulse-shaping amplifiers, followers, and inverters as far as possible.

Earlier analysis of diode logic brought to light the implications of passive multilevel logic.[6] With the availability of new manufacturing techniques for matrices for 2-level logic advanced methods for efficient design are required to achieve the optimum ratio of logical elements to amplifiers with a minimum of pulse distortion.

Two steps are necessary to minimize a logical network to represent given function matrices: 1. determination of preferred forms, and 2. elimination of redundancy.

PREFERRED FORM

It has been shown that any function may be written either as a sum of minterms N_i or as a product of maxterms Mj.[1] Both forms are directly related as follows:

$$\sum N_i=\Pi Mj \quad N_i'=Mj \quad i+j=2^p-1 \tag{5}$$

The matrix concept deals only with the coefficients of minterms which are ONE's. If such a matrix comprises more ZERO's than ONE's, then the function itself shall be subject to minimization. Otherwise the complement contains less terms and should be processed. As an elementary example the function $A+BC'$ is considered:

$$A \qquad 01010101$$

$$BC' \qquad 00110000$$

$$A+BC' \quad (01110101)=f \tag{6A}$$

$$(A+BC')'(10001010)=f' \tag{6B}$$

Three ZERO digits are contained in the f matrix of equation 6(A). Accordingly, the complement f' involves three terms only and should be processed.

In general, processing of a function f of p variables instead of the complement f', is preferable if the matrix comprises fewer ONE's than ZERO's or fewer than 2^{p-1} minterms. Eventually the basic operation of the available hardware will be the determining factor. Diode matrices and several other components necessarily lead to AND/OR logic as represented by minterm matrices f. Direct or resistor-coupled transistor logic is related to maxterms or the reversed minterm matrices.[1]

ELIMINATION OF REDUNDANCY

Minimization of a logical function requires the elimination of redundancy. Redundancy exists if two terms have dummy indexes which differ by only one bit of their binary expression, that is, if

$$i-i^*= /2^k/ \qquad k=0, 1, 2, 3\ldots \tag{7}$$

It is believed that this sufficient condition has not been stated previously in such explicit form and it leads to several routines for minimization.

If different pairs of minterms, $i_1i_1^*i_2i_2^*$, satisfy the simultaneous equations 8(A) and (B) for different values of k, then the redundancy is of a higher order and the variables related to the values of k are redundant.

$$i_1-i_1^*=i_2-i_2^*=2^{k_1} \tag{8A}$$

$$i_1-i_2=i_1^*-i_2^*=2^{k_2} \tag{8B}$$

From a hardware point of view paired minterms required a single gate instead of two gates if a single variable is redundant. If both equations 8(A) and 8(B) are satisfied, the four gates required may be substituted by a single gate with all but the two redundant inputs.

REDUNDANCY IN FUNCTION MATRICES

It is possible to make a systematic search for redundant terms in the following manner.

If the dummy index corresponding to ONE in the function matrix contains at least one bit which is ZERO (when expressed in binary form), then permuting these ZERO's to ONE's one at a time, will indicate the paired indexes i^* immediately. It is necessary only to check that for any of these paired indexes, the coefficients in the function matrix are ONE.

It has been emphasized previously that each bit of the dummy index is related to a certain variable by a weight of a power of 2. Therefore a suitable matrix can be established to indicate the redundant variable for any pair of minterms. For an elementary case of three variables, A, B and C, the matrix $[r_3]$ may be derived as follows. If there is a coefficient $F_0=1$ corresponding to $i=000(b)$, then the pairs to be investigated are $i^*=001$; 010; $100(b)=1$; 2; 4. Weighting $A=1$, $B=2$, $C=4$, allows each variable to be placed in the appropriate column to indicate directly the redundant variable.

$$i=\begin{array}{cccccccc}0&1&2&3&4&5&6&7\end{array}$$

$$i(b)=\left\{\begin{array}{cccccccc}0&0&0&0&1&1&1&1\\0&0&1&1&0&0&1&1\\0&1&0&1&0&1&0&1\end{array}\right\}\begin{array}{l}\ldots C\\\ldots B\\\ldots A\end{array}$$

$$[r_3]=\begin{bmatrix}1&A&B&&C&&&\\&1&&B&&C&&\\&&1&A&&&C&\\&&&1&&&&C\\&&&&1&A&B&\\&&&&&1&&B\\&&&&&&1&A\\&&&&&&&1\end{bmatrix}\tag{9}$$

In order to determine if any redundancy exists, only a matrix multiplication of $[r]\times[f]=[rf]$ is required. This yields the redundant variables. Examples are contained in the Appendix II together with a matrix $[r_6]$ for minimization of six (or more) variables.

General Rules for Minimization of Function Matrices

EXISTENCE OF REDUNDANCY

By definition, redundancy exists in the minterms corresponding to the terms of a row of the $[rf]$ matrix whenever a variable occurs in this row.

ROW REDUNDANCY

The redundancy expressed in a row is covered by other rows if every term in this row occurs in a column which includes at least one other term. Owing to the method used in deriving the rf matrix, a variable will always occur in the same column as a ONE in another row. In checking for redundancy of rows, it is therefore necessary only to check if the ONE in that row has a variable from another row in its column.

GENERAL PRINCIPLES

1. By definition, if a row includes a ONE and a variable, that variable is redundant in the pair of minterms corresponding to the appropriate columns.

$$\begin{array}{llll}
[f] & 00\boxed{\begin{array}{c}11\\1A\end{array}}0001 & 00000001 & \\
[rf] & & & BC'D'\\
 & \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots & & \text{(redundant row)}\\
 & \qquad 1 & \qquad D & ABC\\
 & & & \ldots\text{(redundant row)}\\
\cline{4-4}
 & & & B(C'D'+AC)
\end{array}$$

(A is redundant in $A'BC'D'+ABC'D'=BC'D'$)

2. More than one variable in a given row indicates a NOT condition of these variables multiplied by the minterm of any of the occupied columns with these variables deleted. This is self-evident as shown in the following example:

$$\begin{array}{lll}
[f] & 01010100 & \\
[rf] & \boxed{1\ B\ C} & A(B'+C')\\
 & \quad 1 & \\
 & \qquad 1 &
\end{array}$$

This indicates that B is redundant in $AB'C+ABC'$, and C is redundant in $AB'C'+AB'C$. This leaves $AC'+AB'=A(B'+C')$.

3. (n) variables in a given column indicate an OR condition of the permutations of these variables taken $(n-1)$ at a time, multiplied by the corresponding minterm with these variables deleted. This is also self-evident as follows:

$$\begin{array}{lll}
[f] & 00000001\ 00010101 & \\
[rf] & \begin{array}{|cccc|}\hline 1&&&D\\&1&&C\\&&1&B\\\hline&&&1\end{array} & \begin{array}{l}ABC\\ABD\\ACD\\\hline A(BC+BD+CD)\end{array}
\end{array}$$

from paragraph 1 of this section, this is equal to $ABC+ABD+ACD=A(BC+BD+CD)$

4. If a number of variables occur simultaneously in a column and a row, and if the significant variables of the minterms in each case are identical, then the redundant variables are redundant simultaneously for all the minterms in the appropriate columns.

$$\begin{array}{lll}
[f] & 00000101\ 00000101 & \\
[rf] & \boxed{1\ B\qquad D} & AC(B'+D')\\
 & \quad\boxed{\begin{array}{ccc}1&&D\\&1&B\\&&1\end{array}} & AC(B+D)\\
\cline{3-3}
 & & AC
\end{array}$$

$AC(B'+D')$ (paragraph 2), $AC(B+D)$ (paragraph 3) $AC(B'+D')+AC(B+D)=AC$.

RULES AND PROCEDURE

In order to achieve optimum minimization, the following must be carried out:

1. Search for columns and rows combining the same variables and apply rule I.

Rule I. If the same variables occur simultaneously in a column and in a row, and if at least one of the columns containing the terms of the row under consideration, and one of the rows containing the terms of the column under consideration, include a common ONE, then the minterms corresponding to any relevent column omitting all the variables involved should be written down as part of the minimized expression.

2. The next step is the elimination of redundant rows by the application of rule II.

Rule II. Starting from the topmost row, rows which have not been involved in rule I and in which the ONE occurs in a column which includes a variable from another row, should be deleted, one at a time, and the result of these deletions taken into account in deleting further rows.

3. The next steps are to apply rules III, IV, and V in succession, and finally to add together all the expressions obtained.

Rule III. If n variables occur in a column, the reduced term for the minimized expression consists of an OR condition of the permutations of these variables taken $(n-1)$ at a time, multiplied by the corresponding minterm with these variables omitted.

Rule IV. If two or more variables occur in a row, the reduced term for the minimized expression consists of a NOR condition for these variables multiplied by the minterm of any of the occupied columns with these variables omitted.

Rule V. If only one variable occurs in a row, then the minterm corresponding to the column containing the variable should be written down in the minimized expression, omitting the variable in question.

Conclusions

A matrix equation, called expansion theorem, has been derived to compute the function matrix or truth table of a logical network expanded by adding a new input representing another independent variable. Its particular application is to determine the function matrix of combined moduli similar to the numerous transistor or magnetic blocks used in modern digital systems.

The inversion of this expansion theorem leads to a matrix routine for minimizing logical networks whereby the product of function matrix and a standard redundancy matrix gives directly the terms containing redundant variables.

It is believed that the methods offer considerable advantages in the design of complex logical networks as experienced in code translators, digital displays, or printing devices.

Application of the methods are shown in the appendixes for problems of various complexity.

Appendix I. Developing a Function Matrix by the Expansion Theorem

As an example of the use of the expansion theorem the function matrix of a chain of NOR circuits is calculated. Each NOR circuit has two inputs, the first circuit having the inputs *A* and *B*. Its output is connected to the following NOR circuit and a variable *C* is introduced as the other input.

Referring to Table I, the function matrix for the first level may be written immediately from Y_1:

$[f_{(2)}]=(1000)$

To determine the output at the second level of a NOR circuit requires application of (3), where $[g]=(1000)$

$$\begin{bmatrix}G_t\\ G_{t+4}\end{bmatrix}=\begin{bmatrix}1&0\\0&0\end{bmatrix}\times\begin{bmatrix}0111\\1000\end{bmatrix}=\begin{bmatrix}0111\\0000\end{bmatrix}$$

$[f_{(3)}]=(01110000)$

Following the third level with another variable as input together with $f_{(3)}$, the function matrix $f_{(4)}$ may be obtained similarly:

$$\begin{bmatrix}G_t\\ G_{t+8}\end{bmatrix}=\begin{bmatrix}1&0\\0&0\end{bmatrix}\times\begin{bmatrix}10001111\\01110000\end{bmatrix}=\begin{bmatrix}10001111\\00000000\end{bmatrix}$$

$[f_{(4)}]=(10001111\ 00000000)$

It will be noted that the next higher function matrix $[f_{p+1}]$ is

$[f_{(p+1)}]=[f'_{(p)},0_{(p)}]$

Accordingly:

$f_{(5)}=(01110000\ 11111111\ 00000000\ 00000000)$

$f_{(6)}=(10001111\ 0000000\ 11111111\ 11111111\ 0000000\ 0000000\ \ldots 00)$

Appendix II. Minimization Chart and [r]-Matrix for Six or More Variables

Table II contains the [r]-matrix for six variables and may be expanded as follows:

row 00, column 100	variable *G*	r_7
row 00, column 200	variable *H*	r_8
row 00, column 400	variable *J*	r_9
row 00, column 1000	variable *K*	r_{10}
row 00, column 2000	variable *L*	r_{11}

Similar to the matrix [r_6] the variables continue diagonally with appropriate submatrices [r_6].

In order efficiently to handle problems of higher complexity the matrices are written for those columns only in which the function matrix has its coefficients $F_t=1$. At the top of the matrix the dummy indexes are listed in octal and/or decimal notation similar to appendix III, problem 3. Then from the matrix [r_6] or its expansion for high orders the appropriate binary products of R_tF_t are formed and placed properly.

For reference purposes the rules applicable for each case have been listed in the problems in Appendix III.

Appendix III. The Solution of Minimization in Logical Design

In order to facilitate a direct comparison of this method with other contemporary attempts towards the same goal, the following examples which have been taken from recent publications by other authors, are given.

Problem 1.[7] Translating the valid combinations into a function matrix yields

[f]	(00011101 10011001)	Significant terms	Rule
[rf]	1 D	AB	I
	1A D	$B'CD'$	IV, II
	1 B		II
	1 D		I
	1 C	$A'B'D$	V
	1 C		I
	1		II
	1		II

The minimized form is the sum of the significant terms and may be further reduced by conventional methods $AB+B'CD'+A'B'D=AB+B'(CD'+A'D)$.

Problem 2.[8] To determine the significant form of a 4-variable case with the truth table $i=0, 4, 6, 7, 10, 14, 15, 17$ in octal notation for $F_1=1$:

[f]	(10001011 10001101)	Significant terms	Rule
[rf]	1 C D	$A'B'$	I
	1 D		I
	1A	BCD'	V
	1 D		II
	1 C		I
	1A		II
	1 B	ACD	V
	1		II

Problem 3.[9] The dummy indexes i of the minterms are given in decimal notation as $i=0, 1, 2, 3, 7, 14, 15, 22, 23, 29, 31$. In obtaining the function matrix the columns are written in decimal (d) and octal (o) notation and limited to the columns containing $F_i=1$.

$$
\begin{array}{lll}
i(d) & 00000 & 112223 \\
 & 01237 & 452391
\end{array}
$$

$$
\begin{array}{lll}
i(o) & 00000 & 112233 \\
 & 01237 & 676757
\end{array}
$$

[f]	(11111 111111)	Significant terms	Rule
[rf]	1AB	$C'D'E'$	I
	1 B		I
	1A		I
	1C		II
	1 D E	ABC	I
	1A	$BCDE'$	V
	1 E		I
	1A	$BCD'E$	V
	1 D		I
	1B	$ACDE$	V
	1		I

The column of significant terms is equivalent to the minimum sum.

Volt-Second Transfer Efficiency in Fast-Response Magnetic Amplifiers

Part II. N^2/R as a Design Parameter

T. J. PULA
ASSOCIATE MEMBER AIEE

G. E. LYNN

J. F. RINGELMAN
ASSOCIATE MEMBER AIEE

THIS PAPER presents the final portion of a study to extend the volt-second control approach in considering the effects of signal circuit resistance and nonideal flux-current loops for fast-response magnetic amplifiers.[1,2]

In the first portion of the investigation, volt-second transfer efficiency measurements were used to demonstrate the nature of N^2/R as a basic reactor parameter. This knowledge and the assumption of constant average incremental ampere-turns for complete reset were then used in deriving expressions which indicate the complementary relationship existing between volt-seconds and ampere-turns in magnetic amplifier control.[3]

The object of this concluding portion of the study is to substantiate the ideas already developed by correlating the measurements of incremental volt-second transfer efficiency from part I[3] with gain measurements for a specific fast-response magnetic amplifier.

Illustrative Fast-Response Amplifier

The fast-response amplifier chosen to demonstrate this correlation has been under development by the authors for several years and has been designated the Hybrid III amplifier. The name is in a sense generic and is derived from a somewhat hopeful assumption that the amplifier weds a first stage, which is (to a first-approximation) ampere-turn controlled, to a second stage, which can be considered largely volt-second controlled. That neither of these conditions is ever totally satisfied in the amplifier is demonstrated in the paper.

CIRCUIT OPERATION

The circuit for discussion, shown, in Fig. 1, is a 2-stage push-pull amplifier with d-c reversible polarity output. The second stage is a push pull arrangement of Ramey-type circuits. Angle volt-second control of each half of this stage is provided by a Logan-type circuit.[4] The basic design requirement for this type of control is that the "driving ampere-turn" value for the gate circuit of the first stage must be less than the "threshold ampere-turn" value for the control circuit of the second stage.[4] When this requirement is satisfied, substantially all of the volt-seconds from E_{ac} are absorbed by the first stage reactors until they fire. The amount of E_{ac} volt-seconds thus absorbed, furthermore, is determined by the initial flux condition of the first stage cores as set by the control provided to the Logan circuit. After these first stage cores fire, the remaining volt seconds from E_{ac} are applied to the second-stage control winding in series with all interstage voltage drops.[5,6] It is the inevitable existence of these voltage drops which precludes the possibility of true volt-second control.

Paper 58-173, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Pittsburgh, Pa., October 26–31, 1958. Manuscript submitted October 30, 1957; made available for printing August 7, 1958.

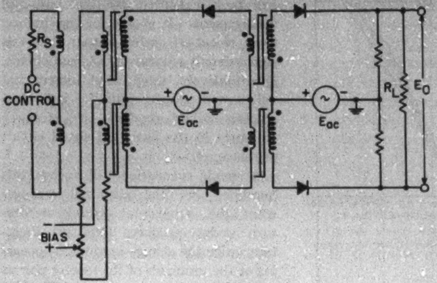

Fig. 1 (left). Circuit of Hybrid III fast-response magnetic amplifier

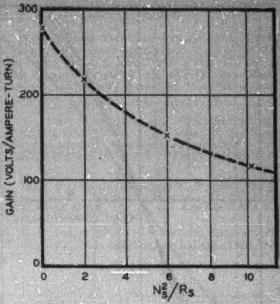

Fig. 2 (right). Volts per ampere-turn as a function of N²/R for a Hybrid III

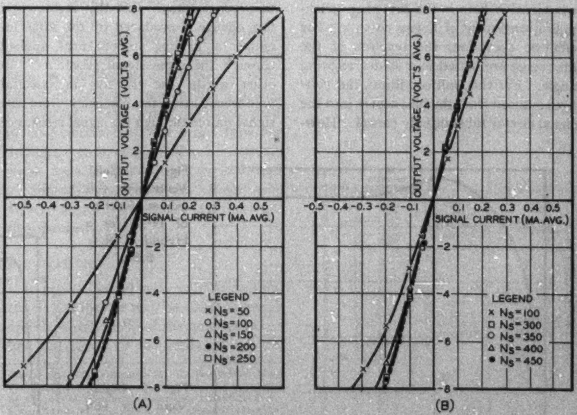
For fast-response design, E_{ac} must exceed nE_{ac}' by a considerable percentage in order to prevent interstage current while the first stage cores are resetting. Therefore, the interstage voltage drops may not be made negligible here and thus even during this time interval determinate volt-second control is not desirable even if it were obtainable. The coupling can be designed in such a way, however, that the transfer efficiency in this interstage coupling loop remains fairly constant while the first-stage cores are allowed to reset without producing appreciable interstage current. Under these design conditions, this second stage merely provides an additional volts/volt gain and the over-all volts/NI gain is essentially a function of the first stage core configuration.

During the prefiring interval of the gating half-cycle for both first-stage cores, the voltages induced into the control circuit are in opposition and approximately equal. However, for any condition other than null, one core fires before the other. Therefore, during the interval in the gating half-cycle after one core has fired, the continuation of flux change in the other core induces volt-seconds into the control circuit. Because of the push-pull, 90-degree bias, reversible d-c character of this circuit, the induced voltage during this period always causes the instantaneous i_s to exceed E_s/R_s. During the period when both cores are being reset, the magnitude of the control current is less than E_s/R_s because of the reactor resetting voltage. However, the reset $\Delta\phi$ obtained (and therefore the ΔE_0) is a function of the magnitude of control current during reset only and not of the average control current. And if N^2/R is increased, the percentage difference between the resetting current and the average control current is increased. Therefore, the V/NI_{avg} gain of such an amplifier decreases as N^2/R increases.

Application of N²/R to Design

The volts/NI gain versus N^2/R for an amplifier of this type is shown in Fig. 2. For convenience, this curve was obtained by varying R_s since the fundamental nature of N^2/R has already been established in part I.[3] The N_c^2/R_c value for which the volts per ampere-turn gain is equal to one half the gain obtained when N_c^2/R_c is equal to zero (extrapolated from the curve of Fig. 2) was picked off as equal to 7.8 (adding 0.50 for bias). The value of gain at $N_c^2/R_c=0$ is designated as $(G_v/NI)_0$. Two practical values were selected to represent minimum allowable R_s (i.e., 8.6k, 3k), and the optimum N_s calculated for each. Volts/NI gain curves were then run for each R_s value by varying N_s. These curves are shown in Figs. 3 and 4, and the resulting calculated curves of volts/volt gain versus N^2/R in Figs. 5 and 6. It can be seen that a maximum volts/volt gain does exist and that it occurs at a value of N_c^2/R_c corresponding to the value yielding G_v/NI equal to 1/2 $(G_v/NI)_0$. This confirms the relationship between volt-seconds and ampere-turns in magnetic amplifier control predicted in part I.

The correlation between the N^2/R producing maximum volts/volt gain and the N^2/R producing 50% incremental volt-second transfer efficiency in the individual reactors employed in the first stage of the amplifier will now be discussed. In part I of this study, it was predicted from mathematical considerations that the maximum volts/volt gain for an amplifier whose input configuration reduces to a Logan circuit should be obtained for an N^2/R corresponding to 50% incremental volt-second transfer efficiency. This will



(A)

(B)

Fig. 3. Output voltage as a function of signal current for a Hybrid III ($R_s = 8.6K$)

B—High N_s

remain true for a 2-stage amplifier if the second stage contributes only a volts/volt gain. In order to check the correlation under investigation, a closer examination of the circuitry in the Hybrid III magnetic amplifier of Fig. 1 is required.

The function of the second stage in merely producing additional volts/volt gain for this amplifier when interstage coupling current during reset of the first-stage cores has been suppressed by appropriate design, has already been discussed. The circuitry requiring closer examination here is the first-stage push-pull arrangement of Logan circuits. For efficient operation, the reactors of the first stage are biased to a 90-degree firing angle. For this null condition, the voltages induced from the bias source into the signal circuit substantially cancel. However, for a general signal condition, one of the input stage cores saturates before the other. For such a general operating condition, the bias source is still attempting to produce half of maximum flux change in each core on each reset half-cycle. Signal, however, is aiding bias in resetting one core but opposing bias on the other core. As contrasted with the null condition then, one of the cores resets by an amount $(\Delta\phi_b-\Delta\phi_x)$ and the other resets by the greater amount $(\Delta\phi_b+\Delta\phi_x)$. The effect of signal, therefore, is to produce $2\Delta\phi_x$. But this incremental flux change is produced by the same incremental driving ampere-turns applied through the same signal resistance. In other words, the effective incremental volt-second transfer efficiency from the signal source through the signal resistance has been enhanced by the push-pull arrangement. It is only for the limiting cases of cut-off or full output that this signal circuit reduces to a Logan circuit. Quantitatively, then, what incremental volt-second transfer ratio for individual reactors should produce 50% transfer efficiency in the push-pull signal circuit of this amplifier?

A simple calculation will answer this question. For the push-pull arrangement, the incremental driving ampere-turn product produces $2\Delta\phi_x$ and, therefore, twice the change in voltage appearing at the terminals of the reactor pair as would be produced across an individual reactor by this same signal current. Thus, if the incremental volt-second transfer efficiency obtained with a matched pair of reactors is 50% in the push-pull configuration, the incremental volt-second transfer efficiency measured in our special test circuit at the same N^2/R for one of these reactors should be 33.3%. (This follows immediately since the resistor reset voltage remains fixed while half of the voltage which appeared at the reactor-pair terminals disappears.)

With this clarification in mind, the correlation obtained can now be assessed. From measurements on the first stage cores, it can be seen from Fig. 5 of reference 3 that a signal circuit N^2/R of 7.5 (with a bias circuit $N^2/R=0.3$) yields an incremental volt-second transfer efficiency of approximately 32%. But this is the same control N^2/R (i.e., 7.8) which produces maximum volts/volt gain when reactors from two such cores are used in push-pull. This close agreement confirms the validity of the results derived in part I from theoretical considerations.

Conclusions

The incremental volt-second transfer efficiency characteristics of reactors composed of square-loop magnetic materials presented in part I have been applied to the design of a modern fast-response

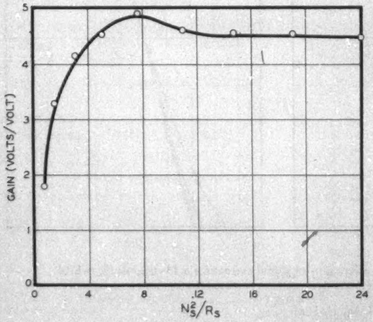

Fig. 5 (left). Volts per volt gain as a function of N^2/R for a Hybrid III (R_s=8.6K)

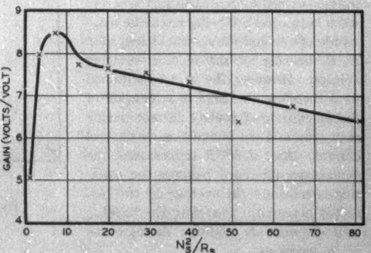
Fig. 6 (right). Volts per volt gain as a function of N^2/R for a Hybrid III (R_s=3.1K)



magnetic amplifier. Close correlation was obtained between the signal circuit N^2/R producing an effective incremental volt-second transfer efficiency of 50% and the N^2/R value yielding maximum volts per volt gain in the amplifier. This confirms the complementary relationship between volt-seconds and ampere-turns in fast response magnetic amplifier control developed in the previous paper from theoretical considerations. Experimental results show that the incremental volt-second transfer efficiency of a fast-response amplifier defines the amplification obtainable with a given configuration. This transfer efficiency is dependent upon the N^2/R of the control circuits, proving this parameter to be as basic to the amplification factor of a fast-response amplifier as it is to the gain-bandwidth product of the older, slower circuits such as the doubler or bridge type.

A Miniaturized Negative-Impedance Voice Repeater Employing Transistors

A. S. HOWELL
MEMBER AIEE

UNPRECEDENTED service demands on the telephone operating companies have emphasized the need for an economical means to extend transmission ranges and to permit the reduction of cable gages in local office areas. As a result, considerable interest has developed in the negative-impedance-type repeater, recently introduced and now finding wide application by the Bell System.

Current demands for such new facilities, however, often create serious space problems. This is particularly true when the required equipment must be installed in existing bays. As one solution to this problem, two miniaturized negative-impedance-type repeaters have been developed. These repeaters employ transistors as their active elements. They are entirely powered from a 48-volt central office battery, thus eliminating any need for bulky power supplies. Modern plug-in printed-wiring-board techniques have been successfully applied in the physical make-up of these repeaters. This makes for compact packaging.

General Description

The type *541* repeaters to be discussed are of the series and the series-shunt type. Their electrical function is to provide transmission gain when inserted in a 2-wire telephone line. Provisions for gain adjustment are adaptable to all line facilities normally found in the telephone outside plant. The circuit design is such as to minimize changes in gain over the range of expected environmental conditions.

The mechanical design includes separate, but companion, plug-in series-type and shunt-type repeater packages. Each unit is of the same over-all size, dimensionally restricted to shelf-mount up to eight repeaters on a standard 19-inch relay rack, within a 3½-inch vertical mounting space. Thus 208 repeater units may be placed in one 9-foot bay of a standard rack.

The series repeater consists of three functional parts: an open-circuit stable negative-impedance converter, a gain-adjusting network, and a line-coupling transformer. The shunt repeater, used in conjunction with the series type for additional gain, consists of a short-circuit stable negative-impedance converter and a gain-adjusting network. Both converters employ transistors as their active elements.

Application

In general, based upon stability factors, the series repeater may be used to recover approximately 50% of the nonrepeatered line loss, up to 10 db (decibels), without singing. However, the series repeater effectively operates on the series constants of the line and introduces an impedance irregularity at the point of insertion. This produces reflections and results in echo effects. The corresponding circuit transmission derating is proportional to the repeater gain and the length of the circuit. While such derating may be acceptable on local circuits it can become serious on long toll-connecting trunks and the use of the series-shunt repeater combination will be required. Such a combination may be used to recover up to approximately 85% of the nonrepeatered line loss and the reflection effects are appreciably reduced.

Use of Transistors

Junction transistors possess desirable properties for use in the negative-impedance circuit to be described. As has been pointed out,[1] their conversion properties in this application are stable and the conversion factor is substantially controlled by the alpha value. The present life expectancy of transistors compares favorably with that of vacuum tubes.

As the state of the art progresses, it is expected that the ideal of practically infinite life may be attained. Coupled with the obvious advantages of economy of space and required power consumption, the choice of transistors in this equipment appears well justified.

Discussion

Series-Repeater Circuit

The series-converter circuit is an adaptation of a common base arrangement described by J. G. Linvill.[1] In the newly developed repeater, circuit constants have been chosen for operation at 40 times line-impedance level. This permits the use of physically small mica capacitors in the gain-adjustment network. The line-impedance step-up takes place in the input transformer. The transistor bases and collectors are supplied through center-tapped inductors. This minimizes impedance shunting of the gain adjustment network and increases the power output when operating at high-impedance levels. Further considerations in the selection of circuit constants include proper temperature bias stabilization, and the maintenance of a substantially constant conversion factor both with respect to load changes and to changes in frequency from 250–3,500 cps (cycles per second). With these circuit constants established, the operating collector currents are less than 1 ma (milliampere) using p-n-p-type *2N44* or similar transistors.

Several considerations are involved in the design of the associated line-coupling (input) transformer. The series-aiding impedance of the line windings must be of

B—Shunt repeater

sufficient value to prevent excessive shunt loss at the lowest voice frequency to be amplified. This value must be maintained with up to 130 ma direct current in the line windings, based upon the possibility of two simultaneous telegraph signals at 65 ma, east and west on composited legs. The d-c resistance and the impedance to ringing frequencies must be sufficiently low for negligible restriction on the loop-signaling range. Line-winding balance must be capable of meeting standard longitudinal balance requirements.

Resistive and reactive components introduced by the input transformer must be compensated for ahead of the network if the gain adjustment is to be directly dependent upon the transformed line impedance. Loss factors contributing to these components are minimized through the use of a laminated core of high-permeability magnetic material in the transformer design. The inclusion of sectionalized windings reduces troublesome distributed capacitance. An interwinding electrostatic shield is provided to minimize stray capacitance couplings. The effective series resistance is substantially independent of frequency over the operating range and is compensated for by a resistor in series with the gain-adjusting network.

Shunt-Repeater Circuit

The balanced circuit of the shunt converter is basically similar to the series-repeater circuitry except that the positions of the input and network terminals are interchanged. No impedance-level transformation is involved. The negative conversion factor, somewhat less than minus alpha, is effectively brought close to -1 by addition of low-value resistances in series with the line-blocking capacitors. When shunt-input resistances are used to supply the collectors and their value is made sufficiently high to obtain negligible shunt-input loss, the supply voltage drop results in insufficient collector voltage to maintain the required operating conditions. For this reason the collectors are supplied through a center-tapped inductor. A high value of inductance is used in order to reduce the shunt losses at ringing frequencies. A shunt capacitor across this inductor limits the converter response at high frequencies.

Connection Facilites

The basic elements of the series repeater are illustrated in Fig. 1(A) and those of the series–shunt combination in Fig. 1(B). In the latter figure, center taps are provided on the two line windings of the coupling transformer and the shunt repeater elements are added in the bridged-T configuration.

A compact connector arrangement results from the application of a plug-in card including six paris of double-side printed contacts. The associated receptacle includes short-circuiting spring for the maintenance of line continuity after the card is removed. The gain-adjusting network is strap-connected to the converter circuitry at the receptacle. It is automatically disconnected when the repeater is removed for insertion into an associated test set. This plan is shown in Fig. 2.

The mounting shelf may be wired for any combination of series and shunt units by employing similar receptacles. Transposition of series and shunt repeat-

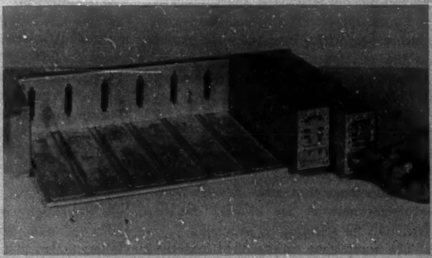

Fig. 6. Shelf-mounted repeater assembly

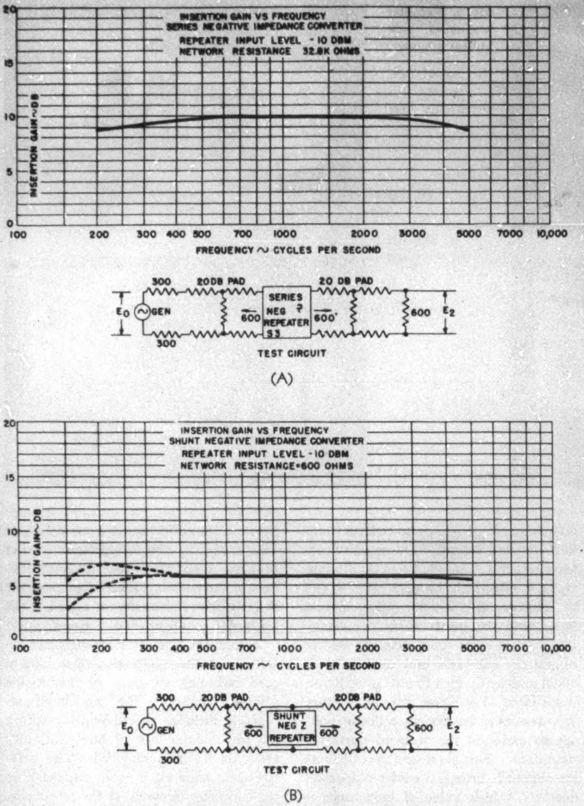

Fig. 7. Insertion gain versus frequency characteristic

A—Series repeater B—Shunt repeater

ers after the positions are established is prevented in the following manner: The receptacles include blank recesses at top and bottom equivalent to those occupied by two pairs of terminals; the series card is keyed opposite to the shunt-repeater card and polarizing insert clips are placed in the extreme upper and lower blank recesses as required. This arrangement is illustrated in Fig. 3.

The complete circuit for the series repeater is shown in Fig. 4(A), and that of the shunt repeater in Fig. 4(B). The graded values of resistance, capacitance and inductance that make up the gain-adjusting network are brought out to terminals for selection by strapping.

The component arrangement and the circuitry is readily adaptable to the application double-side printed-wiring cards. The network strapping terminals are mounted on one side of the card and substantially all components on the opposite side. The input transformer in the series repeater is mounted separately. These cards are fabricated from glass epoxy to minimize the possibility of cracking during the riveting of the more than 40 strapping terminals. They are copper-clad for printed wiring. The plug-in contacts are nickel-rhodium plated to minimize wear.

PACKAGING

The plug-in cards are enclosed in aluminum housing with removable side plates for accessibility of network-strapping terminals and components. This also results in effective voice-frequency shielding of adjacent repeaters. Base-mounted brackets support the printed boards at each end. The line-coupling transformer is separately mounted on one base-supported bracket. Insulated pin jacks for signal monitoring and for the measurement of collector voltages are located on the front face of the enclosures. Fold-flat pull handles are provided to facilitate the removal of the repeaters from the shelf. Two views of the series repeater, with side plates removed, are shown in Fig. 5(A). Similar views of the shunt repeater are shown in Fig. 5(B).

A front view of the mounting shelf with inserted repeaters is shown in Fig. 6.

PERFORMANCE

A typical insertion gain versus frequency characteristic for the series repeater is shown in Fig. 7(A). In this example the repeater is adjusted for 10-db gain at 1 kc when working between 600-ohm pads, each of 20-db attenuation.

A similar characteristic for the shunt repeater is illustrated in Fig. 7(B), in this case the repeater is adjusted for 6-db gain at 1 kc.

Summary of Characteristics

541 A21 SERIES REPEATER

Power supply = 44–54 volts, d-c
Power consumption = 0.6 watt at nominal 48-volt d-c
Power-output level = +10 dbm (db referred to one milliwatt), maximum
Total harmonic distortion, per cent:

Power Output	6-Db Gain	10-Db Gain
+0 dbm	1.4	1.9
+5 dbm	2.1	2.9
+10 dbm	2.6	4.0

Operating ambient temperature = 0 C (degrees centigrade) to +55 C
Gain change at maximum ambient temperature = +0.2 db maximum
Voice-frequency response = +1.0 db, −2.0 db, 250–3,500 cps (referred to 1-kc value)
Nominal maximum gain (resistive terminations) = 10 db
Noise level (*F1A* weighting) = less than 15 dba (db adjusted)
Over-all dimensions = $3^1/_{16}$ inches high x 2 inches wide x $9^1/_2$ inches long

541 A31 SHUNT REPEATER

Power supply = 44–54 volts, d-c
Power consumption = 1 watt at nominal 48-volt d-c

Power-output level = +10 dbm, maximum
Total harmonic distortion:

Power Output	Per Cent Distortion at 6-Db Gain
+0 dbm	0.032
5 dbm	0.25
+10 dbm	1.1

Operating ambient temperature = 0 C to +55 C
Gain change at maximum ambient terminations = +0.4 db, maximum
Voice-frequency response = ±1.0 db, 250–3,500 cps (referred to 1-kc value)
Nominal maximum gain (resistive terminations) = 6 db
Noise level (*F1A* weighting) = less than 15 dba
Over-all dimensions = $3^{1}/_{16}$ inches high x 2 inches wide x $9^{1}/_{2}$ inches long

Conclusions

The described designs illustrate a plan of miniaturization made possible by circuit application of the versatile transistor in conjunction with printed wiring. The plug-in units constitute compact, lightweight but rugged equipment enclosures. They are readily manufactured. Over-all circuit shielding is accomplished and all components are accessible. This same plan also may prove advantageous in the packaging of other equipments.

It is believed that this equipment will prove of value in meeting the requirements of telephone companies for an economical means to extend transmission range within their service areas.

A Review of Telephone Development in Western Europe and in Underdeveloped Areas

G. D. WALLENSTEIN
MEMBER AIEE

THIS PAPER represents a look at telephone development around the world. Emphasis is placed on some outstanding European contributions to the art of telephone transmission. An appraisal of telephone growth potential in the lesser developed countries is also included.

Telephone Communications Development in Europe

During the last 80 years there has been much interchange of ideas between European and American communications people. Two world wars and increasing mobility have contributed in making this one world from the standpoint of technological know-how.

Nevertheless, there are outstanding characteristics and trends in modern European telephone transmission systems which are not encountered in North America. The reasons for such differences may be classified as follows:

1. Several relatively small countries want to foster their own system development and supply.
2. In many countries telephone service remains a luxury because of low average income.
3. Ideas practical for high-volume application have no appeal where the number of salable systems is low, a result of the foregoing conditions 1 and 2.
4. Separate national developers tend to use raw materials and techniques available in their country and thus avoid import.
5. War-time destruction made much telephone plant useless, thus invalidating a prime incentive for developing communications systems to work on old-style cables and wire lines.
6. The International Telephone and Telegraph Consultative Committee (CCITT) establishes recommendations for international backbone circuits in Europe. While this is an absolute necessity in view of the divergent national interests, it tends to restrict such nonconforming developments for the shorter route traffic as have appeared on the American market.

What are the more interesting European developments generated in this way? This paper describes some of the more important developments and ideas of recent years. It is based on the writer's own impressions and is not intended to be a complete list.

Carrier Frequency Cables for Large Number of Telephone Channels

In the industrial area of Western Europe, many cities require heavy telephone trunk routes of relatively short length. In the late 1930's high-grade paper-insulated cables and associated carrier systems similar to the Bell system's type *K* were introduced

Postwar development took advantage of improved insulating materials and manufacturing methods which resulted in a high-frequency balanced type of cable not used so far in North America.[1] Up to 120-channel transmission is now practical on each balanced pair in a multipair cable exclusively designed for carrier use. Noise and crosstalk control is such that good toll standards are met without compandors at the terminals. Transmission attenuation is much lower than that of paper-insulated cables as shown in Fig. 1.

These cable systems are the backbone of Western Germany's toll network, and are used in other countries of Western Europe.[2] Their exploitation has evolved from 24 to 48, then 60, and now 120 channels by progressive improvements.

Cable construction is in multiples of star quads. Typical sizes are 7-quad and 12-quad. One type provides 8 quads plus one coaxial tube in the center. The conductors are 1.3-millimeter (16-gage) copper. Fig. 2 shows the conductor arrangement in the 7- and 8-quad sizes. Fig. 3 illustrates a short length of the 7-quad size showing construction details.

Repeater sections of 12 miles with a section loss of about 60 db (decibels) at 252 kc have been standard for the 60-channel system. The transmission fre-

G. D. Wallenstein is with the Lenkurt Electric Company, San Carlos, Calif.

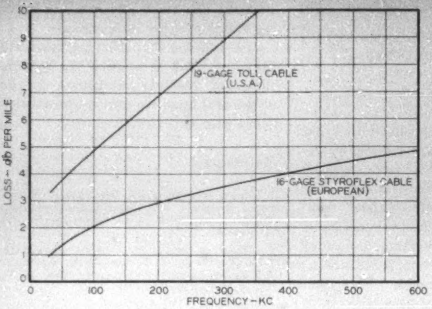

Fig. 1. Comparison of the attenuation characteristics of European manufactured Styroflex toll cable (16 gage) and American 19-gage toll cable. The European cable is usable up to about 600 kc. The American cable has a practical upper limit of less than 300 kc

quencies follow the CCITT recommended 12-channel group scheme. A 60-channel system contains five such groups in the following ranges:

12 . . . 60 kc
60 . . . 108 kc
108 . . . 156 kc
156 . . . 204 kc
204 . . . 252 kc

This scheme allows no space between groups, a fact which has made necessary the development of expensive group-transfer filters to suppress adjacent groups separated by only a few hundred cycles in frequency.

The introduction of a second 60-channel block over the same 12-mile repeater sections was made possible by the use of Styroflex-insulated cable types; see Fig. 3. (Styroflex is an oriented-molecule form of polystyrene.) A pair in this cable has about the same loss at 550 kc as paper-insulated pairs have at 250 kc. This made it possible to use a complete standard 60-channel supergroup in the range 312–552 kc on routes with the new cables. The gap of 60 kc between the two 60-channel allocations offers an unusually economical chance for group transfer.

Control of crosstalk is a major problem on these cables. The two directions of transmission are handled by two separate cables. Even so, within one cable sheath, the combinations of capacitive and electromagnetic couplings add up to

$$\frac{n}{2}(n-1)$$

where n is the number of pairs. For a 24-pair cable, this figure is 276. Despite very rigorously applied specifications for the manufacture of these cables, it is necessary to use crosstalk-balancing devices, one for each repeater section. The importance of capacitive balancing may be illustrated by the fact that as little as a 4-micromicrofarad capacitive coupling causes a far-end crosstalk-coupling loss no better than 70 db. With capacitor-balancing panels it is possible to increase the far-end crosstalk-coupling loss to about 75 db or better for all combinations over the length of one repeater section. These values apply at the highest transmitted frequency.

The question arises whether this technique is indeed more economical than the use of cheaper voice-frequency cables with compandored channels to offset crosstalk. The relative high cost of a precision-manufactured high-frequency cable and of balancing the pairs can be prorated over 120 channels, whereas no more than 24 channels can be operated on the compandored systems customary in the United States. On the other hand, in American systems the two directions can be handled by two pairs in the same cable sheath compared to separate pairs in two parallel cables for European systems. Hence for the European systems there is a higher first cost. However, it would appear that the five times greater channel capacity and the saving of two compandors in each channel gives the edge to the European-type cable system. This comparison applies to new cable installations only.

Even if costs were equal, the European preference would be in favor of non-compandored toll-quality transmission techniques. The CCITT has not so far accepted compandors as a permissible tool for meeting noise and crosstalk requirements. International circuits must be built up with compatible channel terminals at each end. If a compressor were used at one end, a corresponding tracking expandor would be needed at the other. This would be a further complication of international technical agreements, and would impose an economic penalty on that part of the circuit which uses transmission facilities not requiring the compandor advantage. The alternative is to connect circuits at voice frequencies so that both channel

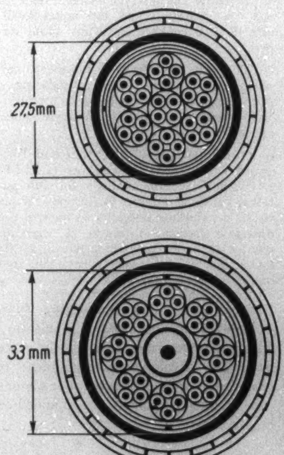

Fig. 2. Conductor and quad arrangements in 7- and 8-quad Styroflex cables. The 8-quad cable also contains a coaxial transmission line

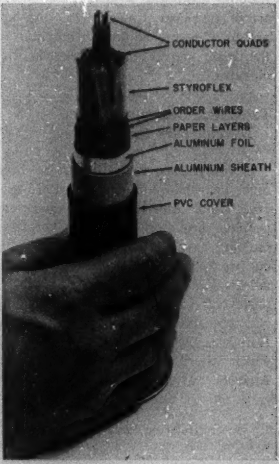

Fig. 3. Construction of latest type 7-quad cable. In addition to the quads, order wires are placed between outer layers of paper insulation

terminals would always be under control of one administration. However, this is a backward step and would again be felt as a hardship.

It is evident that these high-channel capacity balanced-pair cable-carrier systems are an excellent solution for Western Europe's telephone traffic problem. They fit into the already standardized group-transmission scheme, are economical to operate, and are capable of expansion with well-proved techniques.

SHORT-HAUL CARRIER SYSTEMS OF UNCONVENTIONAL DESIGN

The impact of CCITT recommendations has been a freezing of system transmission parameters such as 4-kc channel spacing, standardized 12-channel group frequencies, and connecting impedances. Officially these apply only to international circuits. Some manufacturers prefer to stay within these recommendations regardless of a system's field of application; others venture into nonconforming fields for short-haul transmission.

A large amount of research and economical analysis has been expended to find the least expensive carrier-system design for short trunks. So far it seems that successful results have come in those cases where the telephone administration has requested the manufacturer to meet a particular set of conditions on certain types of cables (occasionally also on open-wire lines). The answer in those cases has been to provide a comparative price tag for each kilocycle of transmission spectrum versus cost of channel filters.

For the past 5 years, the Dutch telephone administration has been using a short-haul carrier system developed to its specifications. This was the result of a study conducted by Dutch and French telephone system development engineers.[3] They decided that the system should be usable on old carrier-operated cables as well as on newer types and that it should conform to CCITT recommendations with respect to quality. Double-side-band transmitted carrier as well as compandors were to be avoided. With these limitations, the approach was to save equipment cost by relaxing filter requirements.

Examination of the contribution of channel filter cost as a function of channel-frequency spacing led to a clear advantage for a carrier allocation in steps of 6 kc. Carrier terminal cost with this spacing is about one third of that with 4 kc according to these studies.

When such a system is applied to balanced or coaxial cable, its relative waste of frequencies will eventually wipe out the terminal equipment savings for circuits beyond a certain length. However, the study here shows that both these types of cables can be advantageously exploited, with their 50% excess frequency spectrum, up to lengths in excess of 60 miles. This is considerably beyond the main target for short-haul economy.

Similar systems, some using 8-kc spacing between channels, are now in use in most countries of Western Europe. The generally accepted prove-in point is at about 40 kilometers (25 miles) length. For shorter circuits, loaded voice-frequency cable pairs are still predominant.

A compromise with CCITT recommendations incorporated in these systems is their group allocation between the frequency limits of standard bands. This eases the transfer of such short-haul system groups in and out of larger capacity toll-carrier systems.

In Germany it is considered that these low-cost systems have made their contribution to encourage quick build-up of facilities by expanding transmission over old cables. But normally, growth of channel requirements between any two points is such that it does not pay to deal with 6- or 8-channel carrier systems. The 12-channel groups forming 120-channel cable or 960-channel coaxial systems are just about the lowest economical increment. On these facilities, frequency spectrum is considered too valuable to trade against savings in channel terminal costs.

It seems that there is no single correct answer to the question of what constitutes the cheapest short-haul carrier operation. Geography, importance of old plant investment versus new, local costs of equipment supply, projected-channel cross section: these are key factors in directing the telephone company's choice. At the present time in Western Europe, there are two schools of thought on this subject. One of these favors unconventional, low-cost equipment design, while the other favors the most efficient utilization of the transmission facility.

ADVANCES IN FILTER DESIGN

With outside system parameters generally standardized, European manufacturers' laboratories tend to concentrate on finding new tools to save money in carrier-equipment detail. Chief targets of attack have been the filters; not only channel filters, but also group filters since these are widely used in carrier-group transfer applications. Attempts to reduce filter costs can be classed in three categories:

1. Cost reduction in material and labor on filters of conventional design.
2. New design approaches to get the same filter results as before with fewer elements.
3. Active filters.

Conventional filter cost reduction has a fairly long history. The introduction of ferrites had its origin in Europe, no doubt stimulated by a drive to cut costs. Cheaper capacitors also are being used. The improvement of manufacturing techniques has allowed not only the complete replacement of the previously necessary mica capacitors by cheaper foil capacitors but in many places has also allowed the use of specially treated paper capacitors.

The improvement of the sintering procedures and the development of new ferrite materials allows the use of ferrite pot cores in favor of usually more expensive winding methods for conventional coils. The provision of inductance adjustments by slugs, films with magnetic material of varying thickness, or adjustable nonmagnetic shunts allows for final adjustment of the filters in the sealed enclosure and eliminates the job of capacitor padding.

The miniaturization of components allows for savings in cans, mounting, etc., and savings on over-all volume and is, as such, an independent factor in cost reduction.

One cost-saving design approach favored for some years has been the calculation of filter networks with equal inductance coils. Several calculatory transformations of the original design are performed until all coils in a given network are identical. However, this approach has lost ground with the introduction of the new adjustable ferrite pot cores.

More recently a heavy concentration on improved and cheaper designs of band-pass filters has taken place. The design according to the formulas published by Zobel[4] in 1923 has been more and more abandoned in favor of the design principles first laid down by Cauer[5] (1931). Cauer's design approach is complicated and difficult to apply. But recently a series of tables and monograms have been worked out which make it usable for routine filter problems.

Another significant step forward lies in the incorporation of the so-called "zig-zag" band filters. The special feature of these zig-zag filters is that with them coils can be saved at the expense of capacitors and vice versa. The final solutions, derived by a combination of these design methods, contain considerably fewer elements than conventional band filters. The additional big advantage is that they are easier to equalize; i.e., require less components in the equalizer.

Still another very promising approach under study is the provision of high attenuation peaks by equipment separate from the filter network. The peaks are achieved by separate magnetostrictive resonators. Such resonators can be made with Q's well in excess of 5,000. They considerably ease the design of band filters with extremely steep flanks. Carrier-frequency group-transfer filters, with separation bands of a few hundred cycles at pass-band frequencies in excess of 100 kc, is one of these cases.

Several leading manufacturers seem to put emphasis on the design of so-called active filters; i.e., filters where amplifying elements are incorporated to compensate for inherent losses. They permit such very lenient approaches to the over-all design that actually active resistance-capacitance filters can be used in carrier systems.

General Technological Advancements

The search for raw materials found at home is traditional in Central Europe where copper, nickel, and other basic materials have to be imported. The use of aluminum in wires and cables has made great progress.

Aluminum also is now widely used as cable sheath. Techniques have been developed to extrude the sheath over the cable, which provides a better fit than the previous methods. It is customary to cover the aluminum with a polyvinyl-chloride outer sheath which protects it from installation damage and corrosion.

Another European development has advanced the design of low-loss high-frequency coaxial cables. It uses a spiral-wound multilayer Styroflex insulation between the copper inner conductor and the aluminum sheath. It comes in a range of sizes up to several inches in diameter and can be advantageously used for radio and television station antenna transmission lines.

Styroflex has also found widespread application in capacitor manufacture as a preferred dielectric. It combines high dielectric constant with high insulation resistance. These capacitors have largely replaced the traditional mica types. European developments in cables and capacitors are finding increasing acceptance in the United States.

Still confined to relatively limited application is the metalized paper capacitor. This is a self-healing type of great interest in high-voltage applications. There is also a type of lacquer-dielectric capacitor. In this type the dielectric consists of a layer of lacquer baked on the metal foil. The objective here is to push size reduction to the limit. These are examples of the great ingenuity displayed by European engineers.

Customer Service Features Closely Associated with Transmission Development

While we are engaged in the introduction of direct-distance dialing, it is well to appreciate that this application of automatic telephony has a fairly long history in Europe. A large-scale regional direct-dialing network was set up in 1924 in Southern Germany. Similar developments have taken place in the Netherlands, Switzerland, and in Italy. Since the end of the war, progress in the countries of Western Europe has been rapid and consistent. European experience shows that direct-distance dialing acts as an incentive and thus raises the calling rate substantially.

There are other advantages which become apparent with use. Some telephone administrations have found that the fully automatic plant costs little more to keep busy on a 24-hour cycle than it does for the usual ten or so busy hours. Consequently, incentives have been set up to encourage subscribers to place their direct-dialing long-distance calls during the off hours. Rate reductions are very significant and the public has responded very favorably to this feature. Coin telephones suitable for direct-distance dialing have been developed. The customer has visual check of the number of coins he has inserted and realizes his time is up without intervention of an operator. He also has the option of predetermining the length of call by inserting the right number of coins at the start.

It has also been learned from experience that a direct-distance dialed call encountering a busy party presents a serious problem. An irritated subscriber repeatedly trying to make a connection can tie up a valuable long-distance trunk or several tandem trunks. One administration at least plans to overcome this difficulty by offering an optional "recall" feature. This arrangement will take over if the called line is busy, automatically make a connection within seconds after the line becomes free, and recall the calling party at the proper moment. It can be said that the advantages of automatic telephony are being utilized to a very high degree in Western Europe.

One other customer service approach which points up a fundamental difference between Europe and America should be mentioned here. That is the nonexistence of party lines as we know them in the United States. Some European telephone administrations have instead chosen the line-concentrator technique. A typical arrangement is for 3 lines to serve up to 16 subscribers. Usually, no more than 12 subscribers will actually be connected to such a concentrator. Full privacy is assured, and the telephone administration undertakes to allot these connections to subscribers with such calling habits that the resultant service is equivalent to single-party line. In Western Germany this technique has proved economical for subscriber-line lengths upwards of 1.5 miles.

On the whole, telephone service including long-distance facilities are well advanced in those countries of Europe which have their own development and manufacturing facilities, or which are closely collaborating with one of these leaders. However, the telephone density per population is still relatively low in many otherwise advanced countries. It seems that growth is paced by telephone administrations which struggle with political and financial difficulties while a very large segment of the population is either on record or otherwise known to be in the market for telephone service.

The traditional combination of mail, telegraph, and telephone often slows down telephone development. The postal service is considered a must, at any cost, and frequently is supported by income from the telegraph and telephone operations. Since telephony requires a relatively long-term investment in plant, money is difficult to raise where government administrations come and go every few months and where confidence is lacking. This condition is a marked contrast to the widely held notion that people have as many telephones as their cultural and economical status permits.

It appears rather that people as a whole are ahead of their own public administrations. Government-administered telephony is most advanced in a small number of countries which have long traditions of political stability and self-government (Switzerland, Nether-

Vol.
Pt. 1
1959

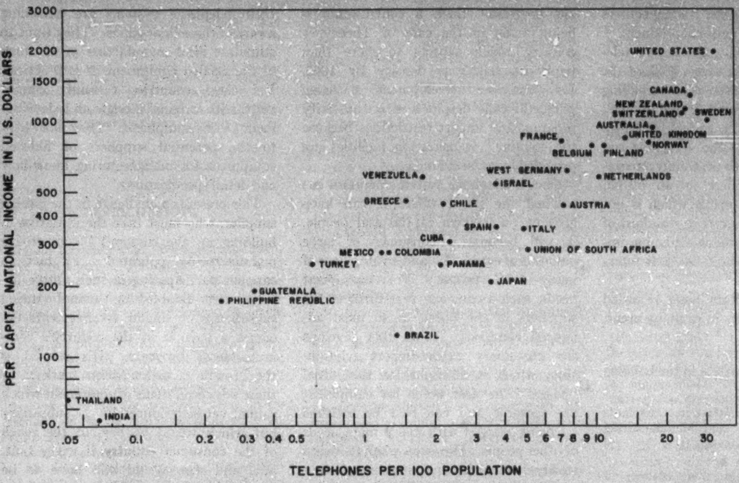

Fig. 4. Although telephone density generally corresponds to per capita income, political and cultural factors often cause considerable differences between countries of equal economic status

lands, Great Britain, and the Scandinavian countries).

Although the decisions on government versus private operation of telephone systems were made many years ago in most parts of the world, there remain a few countries where this is still a major issue. In Italy for example, a system of privately operating concessionaires has been in force since 1925. In these 30 years, the telephone density in Italy was raised ten times, reflecting the most spectacular progress of all countries in per-cent increase of subscribers. Also, local dial-telephone service is approaching 100%, and direct-distance dialing is already effective in larger areas than in many other parts of Western Europe. Now the government is considering taking over all telephone service and has called for a cancellation of the concessions, effective this year.

It will be interesting to watch how this issue is settled. The experience in Italy may have significance for many of the less developed countries around the globe which are now starting out with a system as weak or weaker than Italy's was in 1925.

Telephony in the Underdeveloped Areas

According to official reports, about 200 countries or independently administered areas have telephone service of one kind or another. But only about a dozen countries develop and manufacture telephone transmission systems. These same countries also operate about 85% of the world's telephones.[6]

What happens in the other 190 countries? Is it possible to classify them all as generally underdeveloped, and assume that telephone development is proportional to the standard of living? For a first statistical approach, telephone density and per-capita income have been plotted in Fig. 4. As can be seen, the general trend is unmistakable, particularly in the high-income countries. There is a high positive correlation between per-capita income and telephone usage.[8]

But a closer study indicates that such generalizations do not necessarily account for the position of less-developed countries. For example, Greece and Austria have about the same per-capita income, yet Austria leads Greece in per-capita telephones by a ratio of over four to one. The ratio is 10 to 1 for Japan versus Guatemala, two other countries with about equal per-capita income. Different people have different uses for the same amount of income to spend. Telephone service is more attractive when more people with telephones are accessible to a subscriber. Thus it is a service that feeds on itself. If the local telephone company shows initiative in setting up offices and lines for a growing number of connections, then people will be induced to participate. If, however, there is individual distrust in the quality of public services, people, regardless of income and social stature, will rely on other forms of message exchange, or will remain more isolated from each other.

Telephone density figures alone are not indicators of a whole country's telephone development. For example, the Union of South Africa and Italy have, at the present time, the same density of about 6 in 100 population. But in South Africa, due to the political status of the natives, only about 20% of the population have an opportunity to participate in telephone development. Thus, the true telephone density in that country may be closer to 20 in 100 of the white population. It could then be concluded that South Africa has a more highly developed telephone system than many European countries.

This example also points out that telephone development may be judged in relation to factors such as business activity, rather than population and per-capita income figures. This is particularly true in the early phases of development. There is no country so backward or so disinterested in communication that it could not justify from 2 to 10% telephone density in its big cities. The cities of the Orient are teeming with small and large businesses which exchange messages among themselves, and with many of their customers. In addition, communication between the city and the food-producing countryside is an absolutely fundamental need. The cities must also utilize communications to function as the trading centers for the foreign sale of national products.

From this viewpoint, the lag in telephone development in about 90% of the world's countries is even more appalling than the usual figures would reveal. While it is true that large-scale build-up of communications in the very long run must be in step with a country's economic well-being, there is an initial, basic development possible which is not dependent upon the average standard of living. This development finds its impetus in the big cities and in their interconnecting networks.

Two principal factors have retarded this phase of telephony in so many areas. They are:

1. Lack of native initiative in the building of telephone networks.

2. Lack of outside initiative in transplanting foreign know-how and manufacturing ability.

Native initiative is, of course, a function of economic and political stability. But it is also necessary for a country's political administration to recognize that communications development cannot be turned on and off at will. Where this recognition has been gained, there is usally a nucleus of people for whom telephone development is a lifetime job. These people will develop a plan which requires, among other things, the availability of capital. At this point the program must fight for survival with all the other more or less worthy proposals for spending the public's money. Since the telephone people can promise neither guns nor butter, nor tangible profits for any major pressure group, they do not usually fare very well.

Given time and a few stable years, the telephone system may be substantial enough to grow modestly on its own earnings, at which time its problem will shift to one of preventing its earnings from being siphoned off for use elsewhere. But the most crucial growth period for a telephone system is precisely during its infancy, when it must draw on outside capital. It is like denying milk to a helpless baby, while a starving adult would fight for his own survival.

To spur initial telephone development in the baby phase, outside capital may be brought in, provided there is a native nucleus with a plan and a will to succeed. Where governments manage the telephones, this financing may come in the interest of military necessities such as the North Atlantic Treaty Organization communications program or perhaps as part of a United States foreign-aid program. Such a contribution is being made in the case of Turkey, a country which expects to more than triple its telephone density by 1965. Its subscriber development is being pursued locally despite a severe austerity program and import restrictions because the country's transmission facilities are provided by outside funds.

Once a telephone system operation has reached the point where it can keep growing on its own capital and people, it will become a consumer of large amounts of equipment and an employer of many local people. For equipment needs, such a company first turns to the suppliers in the dozen or so most advanced countries. From this develops the customary export-import relationship, which is all right for the initial phases. The first needs for equipment are sporadic and can best be satisfied by being merged with many more needs of other people. However, when there is a steady demand for equipment in sufficient volume to support a basic manufacturing organization, steps should be taken to develop native manufacturing.

Continued dependency on import can become a major obstacle to a telephone company's growth for the following reasons:

1. The purchasing telephone administration must set up a detailed specification for the foreign supplier to meet. This may or may not be considered necessary by the supplier, but it is always being done to protect the purchaser. Since it is likely that the supplier knows more about the equipment and its applications, this specification becomes an obsession for its authors and calls for unreasonable ingenuity, investigation of marginally important points, and procrastination in tying down the requirements.

2. It is one thing to get an appropriation for telephone expansion in the first place, but quite another to get an import license for equipment and, finally, an allotment of the necessary foreign currency. Telephone organizations waiting for equipment subject to these obstacles may have their plans set back by several years.

3. The cost of equipment is usually higher than it would be if native labor could be efficiently employed.

4. There is no interchange of personnel and little advance knowledge of equipment features as there always is where manufacturing and operating technical people work in geographic proximity and speak the same language.

5. An operation which must depend entirely upon foreign-made material can never become very popular. People do not like to think that their telephone bill makes money for some remote foreigner's pockets.

More and more countries whose administrations are anxious to advance their telephone systems are becoming aware of these limitations. They want to stimulate local manufacture of as much of the needed equipment as is practical. Yet these countries certainly cannot start with original design and development of this equipment. They must look to the potential suppliers of finished equipment for manufacturing know-how and detail specifications.

This presents a challenge to the foreign supplier, who must take the initiative in building up the customer's competitive manufacturing potential. In fact, a supplier participating in such native development establishing manufacturing subsidiaries or similar arrangements becomes a partner in the country's communications program. His reward is the growth of a long-term market for those advanced items of equipment which cannot yet be produced by the subsidiary but which would be beyond the reach of the consumer country if every bolt, nut, and wire would still have to be imported.

There are signs that this approach is finding increased favor. Starting with modest partial assembly operations and progressing gradually towards more intricate production work, telephone communications equipment is now being made in such widely separated countries as Mexico and India, to mention only two. These factories turn out more than needed equipment: They raise a crop of native engineers, technicians, and skilled workers. They contribute directly in making an entire country a better partner in international communications. They help immeasurably to overcome that country's inferiority complex, hence its animosity towards imported technical contraptions.

Ultimately, each country with a multimillion population, and with language, customs, and administration distinct from its neighbors, will have to have a communications manufacturing industry if it wants to have communications. The process will be accelerated in those countries where native initiative is a favorable incentive for the needed foreign investment.

Discussion

Roman Krzyczkowski (Westinghouse Electric Corporation, Baltimore, Md.): This comprehensive paper by Mr. Wallenstein "is not intended to be a complete list" of important trends and developments, hence I should like to concentrate only on the most important problem which, in this discusser's opinion, did not obtain full justice in the otherwise excellent review.

The problem revolves around the question of demand for service: How many circuits must be provided and at what (uninterrupted) distances? Is television transmission involved?

Mr. Wallenstein gives a good description of multipaired cables for working 60 and even 120 channels per pair. However, a look at the map of principal European networks shows that these are still largely in experimental stages and the great majority of high-traffic routes are served by standard coaxial cables. This is, at least partly, a result of the fact that while two separate cables are required for 4-wire working (due to crosstalk difficulties), a single coaxial cable can easily give equivalent capacity. On first costs alone, if the price of 2-tube coaxial is taken as 100, two 4-quad cables capable of taking 60 channels per pair would cost at least 140, and two 7-quad cables, 170. Moreover, the cost of terminal equipments is about the same for the capacities in question and that of line repeaters is actually higher for multipaired installations. Finally there is an almost universal demand for television channels capacity that can be provided in cable only by coaxial techniques.

Extensive studies made show that for capacities of some 300 telephone channels and more, and for medium and long hauls (above, say, 60 miles), the coaxial techniques offer the following advantages over multipaired cables:

1. One cable is required instead of two.
2. Hence the first and annual cable costs are smaller.
3. Duct charge is also smaller.
4. Installation is cheaper and quicker.
5. Transport costs also are lower.
6. Foreign import duties, whether levied per value or per mile of cable, are lower.
7. Quantities of metals are generally smaller, and hence better hedging results against base price fluctuations.
8. Smaller stocks of metals must be carried.
9. Only coaxial cable ensures a possibility of television transmission.

There are also other basic forces at play. Designers of 60- or 120-channel cables fight against natural laws since crosstalk difficulties increase quickly with frequency. But in a coaxial cable the exact converse is true: the higher the frequency the less crosstalk there is to worry about. Thus, existing coaxial cables can easily accept 12-megacycle/second bandwidth. Hence studies are being made to halve existing repeater spacings (from 6 to 3 miles) and thereby to increase threefold capacities of existing installations (from 960 to 2,880 telephone channels) per two coaxial tubes.

It is clear that the cost of fitting 12-megacycle/second equipment on existing cables is only a fraction of a new installation and hence this technique may prove very advantageous to financially harassed administrations.

In specific conditions coaxial techniques can be proved in distances of some 20 miles and capacities of no more than 60 telephone channels.

It may be deduced from the foregoing that the future of European networks will be significantly shaped by competition between coaxial cables and radio links, with ingenious multipaired cables filling only very special requirements.

Coming to other points, it is perfectly true that CCITT recommendations make it difficult to use such techniques as compandors or 6-kc spacings between adjacent telephone channels. On these points Europeans quite often envy American practices. However, once existing networks came into being, any systems incorporating these devices can offer now only very marginal advantages. Careful studies show that not much can be gained from relaxation of CCITT recommendations; especially since the change from 4 kc to 6 kc is not advantageous when the whole system is considered, i.e., a cheaper filter is balanced against wasted space in (expensive) cable.

At least in one country party-line arrangement is well known. In Great Britain 2-party subscribers form a large percentage of the total. On the other hand, concentrators there are only under study.

The close interrelation between telephones and mail has many advantages for the former. Mail normally more than pays its way and can quite often subsidize underdeveloped telephone networks working below their potential capacities. On the other hand, excellent postal arrangements (several deliveries daily, same-day delivery within metropolitan areas of mail posted before 4:00 p.m., etc.) and their low cost are serious competitors to telephone traffic, especially to long-distance calls.

Finally, with regard to telephony in the underdeveloped areas: All major countries in Europe (Great Britain, France, Germany, Italy, Sweden, Belgium, Holland, Switzerland) have their own fully developed telephone industries. Names like Automatic Telephone & Electric Company, Ltd., Siemens, Ericsson, and Phillipps, denote what is best in the telephony field. Also, these and other countries have many plants, some of which are subsidiaries of either American principals (such as International Telephone and Telegraph Corporation or Autelco) or of the foregoing European companies. Both groups of interests foster most actively development of local manufacture. Out of many examples let me quote one: the ultramodern Indian Telephone and Telegraph Company into which the British Automatic Telephone & Electric Company, Ltd., put the best of its knowledge, experience, and good will.

The principal factor which retards the development of telephony in many areas is simply the lack of capital; neither local nor outside initiative are lacking. Suffice it to say, that in many European companies exports (including the export of know-how) exceed 50% of their total turn-overs. What is wanted is peace and an increased standing of living. As the American experience shows, given these two factors, the telephone industry can become the most prosperous undertaking and the quality of telephone service will be unequaled by any standards.

The discusser trusts that these remarks may be found of interest by students of telephony problems in countries other than America as a supplement to the valuable paper of Mr. Wallenstein, who deserves to be congratulated for his initiative in originating this discussion.

G. D. Wallenstein: Mr. Krzyczkowski's discussion of the merits of coaxial over balanced-pair cable transmission could well be the subject of another paper. The stated purpose of the paper was to highlight those European developments which are *different* from United States and Canadian practice. Coaxial systems closely similar to those used in Europe have been fully developed here by the Bell system and have been adequately described in several AIEE papers.[1–3] By contrast, no further development of all-carrier frequency balanced cables has occurred here since the days of the Western Electric *K* System. The improved European multipair systems form the backbone of telephone networks in a good part of Western Europe where they have long left the experimental stage. The official CCIF "General Interconnection Plan 1954–1958" lists many thousands of trunks of this type in existence or to be provided.

Since the presentation of this paper in 1957, there has been one new development of a small-gage coaxial system in England. This type of system, of 300-channel capacity, will bring coaxial techniques economically more in line with balanced-pair cables in applications for smaller circuit groups.

The belief that the mails more than pay their way is not borne out in leading countries of Western Europe such as France and Germany[4,5]. In the United States, difficulties of balancing the postal budget have been well publicized. The point is well taken that some types of postal communication service compete favorably with the telephone. Generally it would be advantageous to see to it that such competition be carried on under different managements than under the same monopoly.

Some British companies have indeed made a good effort in India to assist in the growth of local development and manufacture. In good part this is due to the initiative of the Indian government which places telecommunications equipment manufacture under national control. The point of my paper is to stress that more creative native participation is needed instead of outright export. This approach has not been necessarily considered good business by export-minded manufacturers. The often quoted lack of capital is only a symptom for a lack of initiative wherever there exists capital hoarded and otherwise idle. This is true for many underdeveloped areas and represents a latent immediate potential which could be tapped long in advance of broad-scale improvements in standard of living.

The comments received certainly indicate that this subject could benefit from more exhaustive studies.

The Present Status and Anticipated Progress in the Field of Insulating Materials

THOMAS D. CALLINAN
NONMEMBER AIEE

INSULATING MATERIALS have become increasingly the subject of serious study within recent years. Seven books[1–7] and at least ten full-scale reviews[8–17] on insulating materials have appeared within the last 10 years. These do not include a monthly trade paper, *Insulation*, dedicated wholly to the subject,[18] or the annual *Digest of the Literature on Dielectrics*, published by the Conference on Insulation of the National Research Council.[19]

In addition, *Electrical Engineering*, *Electrical Manufacturing*, *Transactions* of the Institute of Radio Engineers (Professional Group on Component Parts), and the Society of Plastic Engineers present, as a continuing policy, articles on electrical insulation and its uses. Furthermore, the theoretical aspects of dielectrics appear frequently in such accredited organs as the *Journal* of the American Ceramic Society, the *Journal* of the American Chemical Society, the *Journal of Applied Physics*, the *Journal of Chemical Physics*, the *Journal of Physical Chemistry*, *Physical Reviews*, and *Reviews of Modern Physics*. Articles on one or more aspects of dielectrics appear also in European and Asian journals devoted to chemistry, engineering, or physics.

The increasing interest shown in dielectrics as exemplified by publications has been accompanied by a startling growth curve for talks and papers delivered on the subject at annual meetings of learned societies. Both the AIEE and the Institute of Radio Engineers sponsor active programs on insulating materials and their use and evaluation in components. Attendance at symposia has been as high as 400 members and guests. The number of papers per session is usually between four and six, and it is common at the AIEE annual winter meeting to have four to six sessions devoted to insulation topics.

The National Research Council, with a membership of 400 to 500, meets annually to hear about and to discuss electrical insulation. The Electrochemical Society sponsors an annual 3-day symposium on electrical insulation and has a permanent group of 100 members enrolled in electrical insulation division. Meetings of the National Research Council and the electrical insulation division, neither of which require formal written papers, have become so packed with informal talks, disclosures of new materials, and discussions that *Electrical Manufacturing* devoted ten editorial pages to report last year's happenings.

Besides the established society meetings, 1- to 3-day sessions on the subject are being sponsored increasingly by government organizations and universities. This amazing growth of interest in a subject as specialized as electrical insulation bespeaks intellectual problems which numbers of dedicated and well-trained scientists find worthy of attack.

The books which have appeared present the viewpoints of physical chemists (Smyth), chemical physicists (Bottcher), engineering physicists (von Hippel), mathematical physicists (H. Frohlich), and engineers (Whitehead).[1–5] The fact that men of such seemingly diverse backgrounds find themselves in the same field of study arises from the nature of dielectrics considered as an intellectual discipline. It may be studied as a section of chemistry or engineering or physics, without regard to the other sciences, but the subject of dielectrics has depth only when illumined by the laws of all three. Its composite nature may be visualized by Fig. 1.

To the electrical engineer, insulation has always had a functional aspect which has impelled him to make contributions to the subject, not particularly derivable from the more fundamental approaches of the other disciplines. The engineer, interested in dielectrics, has done far more than just adapt available materials to his equipment. His laminated structures, which possess high dielectric strength, have not yet been derived from theoretical foundations. Again, his use of liquid-impregnated solids, while understood empirically, has yet to be quantitatively developed.

To the physicist, the nature of dielectric polarization has proved an intellectual forte and has resulted in predicating theories of energy storage and energy transport in insulating materials. Incidentally, the basic problem

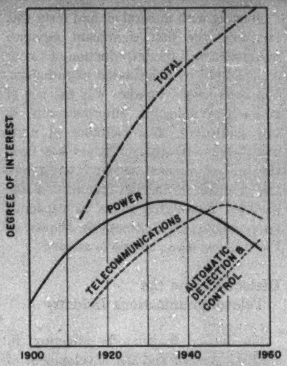

Fig. 2. The contribution of electric power, telecommunications, and automatic detection and control to dielectric studies

of relating the macroscopic properties to molecular ones was the subject of at least 20 published articles last year, and the total number on the subject since the century-old work of Classius and Mossotti is now well over 1,000.

To the chemist, dielectric phenomena have served both as a tool for the elucidation of molecular structure and as an incentive for developing new and improved gases, liquids, and solids. The chemist has found the electrical industry an apt place for pursuing his tendencies toward developing and molecularly engineering new compounds of greater moisture resistance. He also has found that his interest in uniformly fine inorganic structures has been encouraged by the electrical industry and has resulted in the development of not only the high-voltage ceramic insulators, but the magnetic ceramics as well.

Dielectrics has indeed been a fruitful field for all three disciplines and each recognizes the contributions of the others to it. An examination of the forces which have led to the interest in insulating materials and the forces extant today which are motivating further research should permit a critical evaluation of the present state of dielectrics and anticipated progress in the field of insulating materials.

Sources of Industrial Interest in Dielectrics

The development of insulating materials into the subindustry of today has arisen from three enormous forces, namely 1. the electric power industry, 2. the telecommunications industry, and 3. the new industry concerned with automatic detection and control which includes recognition and guidance systems, detectors, memories, computers, and servomechanisms.

The electric power industry had, as its basic proposition, the idea that the generation and transmission of electric power was economically feasible and that the availability of cheap power would result in its exploitation. It is rather difficult today to comprehend the anxiety, fear, and worry which passed, at one time or another, through the minds of the founders of the electric power industry. Today the problems of the industry are ones of finance. Scientific meetings deal with such problems as reliability, life expectancy, and improved distribution techniques, all of which become important only when one is extremely successful.

The telecommunications industry, having as its purpose the reliable transmission of intelligence, has been the second fruitful source of employment for insulation specialists. This force grew, beginning in the second quarter of the 20th century, into all that is now known as electronics. It involved the subindustries of telephony, radio, television, radar, high fidelity, and the movies. While the basic mechanism or driver was the vacuum tube, the insulation specialists found and solved problems in high-frequency cables, capacitors, and hook-up wires.

Automatic detection and control is the third and latest force to motivate dielectricians. It differs from the work of the previous two periods in this respect; rather than adopting materials to sustain high voltages or to pass high-frequency currents without loss, it entails utilizing dielectric phenomena to identify an event. Such an event is compared with one stored in a memory and, depending on the outcome of the comparison, a machine is made to act in accordance with a set of preissued instructions. It would be an understatement to say that this problem is an intellectual challenge equal to that of the previous two forces. It will certainly require an interaction of many disciplines to solve these latest problems.

To suggest the contribution of each force toward developing new insulating materials over the past 58 years, Fig. 2 pictures the general interest shown by investigators through their patents and publications. The figure suggests that there is a strong but declining interest in developing new insulating materials for the power industry at this time and even a slight drop in interest in classical communication problems. But these are specialized views and a decline in interest is to be expected as more and more problems in the field are solved. The general interest in insulating materials has increased over the years as shown by the dotted line. Incidentally, if instead of patents and publications the expenditures of the electrical industry and its suppliers are taken as a measure of the force for developing new insulating materials, there is no observable decline of interest in any one of the sectors.

Dielectrics and the Electric Power Industry

The chief problems of the electrical industry in the first days of its establishment required the development of high-voltage transformers and cables, large generators, and subsidiary equipment such as reactors, power factor correction capacitors, lightning arresters, and circuit breakers.

Some of the problems were solved quickly and satisfactorily. Thus, porcelain bushings, once accepted, have not been replaced. Again, the lead-oxide pellets of the lightning arrester are standardized. On the other hand, the demand for longer life in more compact equipment has led to a continuing demand for new transformers and generators, motors, and high-voltage power-frequency capacitors.

From this viewpoint there were four distinct kinds of insulating materials required: 1. solids for slot armour, insulating cylinders, and turn insulation, 2. enamels for wire, 3. thin separators for capacitors, and 4. liquids as impregnants and coolants.

STRUCTURAL INSULANTS

The high-voltage transformers and the heavy generators and motors required insulation which could resist the severe

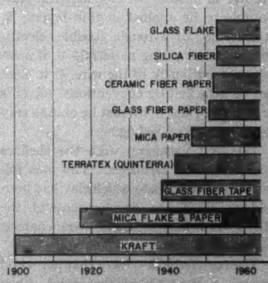

Fig. 3. Structural insulants developed because of electric power needs

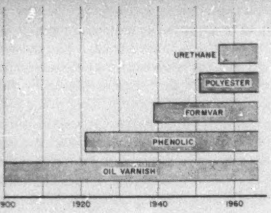

Fig. 4. Wire enamels developed because of electric power needs

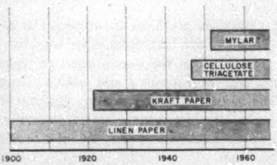

Fig. 5. Capacitor spacers developed because of electric power needs

mechanical and thermal shocks to which the equipment was subjected, which was inert towards moisture, and which had reasonable dielectric strength and moderately low electrical losses. Because heavy electric equipment is prone to be subjected to serious temperature and mechanical overloads, designers of such equipment have demanded that the insulation used be thermally stable. As a result of this demand there has been developed products like terratex and quinterra, alsifilm, glass fiber yarn, glass fiber paper, silica fiber paper, mica paper, synthetic mica paper, and glass flake paper (Fig. 3).

WIRE ENAMELS

The requirements of a good wire enamel are five in number: 1. the material must be able to be applied in thin layers; 2. it must dry to a tough, flexible, electrically nonconducting material; 3. it must adhere tenaciously to the wire, 4. it must not be attacked by conventional solvents or moisture, and 5. it must be able to stay flexible after thermal aging.

The first varnishes were the shellacs and linseed oil varnishes. This was followed by varnishes to which clay had been added. With the development of the alkyd varnishes, synthetic wire enamels became available.

Then came the discovery that polyvinyl formal, a clear transparent solid, when mixed with phenol became plasticized. This mixture in turn could plasticize a phenolic varnish. The enormous success of Formvar wire enamels is deserved.

There have been introduced lately a number of new enamelled wires having thermal stabilities superior to those of Formvar enamel. This historical development of these enamels is shown in Fig. 4.

HIGH-VOLTAGE POWER CAPACITORS

Originally capacitors were of two kinds, air and mica.

The development of the armature or rolled-type capacitor transformed the manufacture of capacitors into a high-speed process. Such a unit had two possibilities for quality improvement which appealed to the chemist; he was able to change the chemistry and thickness of the spacer and he was able to change the chemistry of the impregnant. As a result, over the period of the last 50 years, there have been many worthy improvements in the life, thermal stability, and size of such units.

While paper is still employed as the dielectric, a significant change in the chemistry has occurred. Early theories suggested that fine linen papers should be used, and much work was expended in cleansing the stock; now it is known that select impurities in kraft pulp actually extends the life of liquid-filled capacitors.

Attempts to replace the paper structure with continuous polymer films has had some success. Considerable work was done on adapting cellulose triacetate to high-voltage capacitors, but it was not until the highly uniform polyethylene terephthalate was produced that a significant advance was observed. Furthermore, it has been found possible to make paper uniformly in thicknesses of 0.0002 inch, a reduction of 60%. The uniformity of the paper has been improved enormously in the meantime. These improvements are pictured graphically in Figs. 5 and 6.

LIQUID IMPREGNANTS and COOLANTS

Liquids are employed by designers of electric power equipment to serve as coolants, or to confer dielectric strength, or to store energy. Sometimes the liquid serves multipurposes as shown in Fig. 7. Over the years liquids have been developed having both satisfactory coolant and dielectric properties. They range in boiling point from the Freons up [24.6 C (degrees centigrade)] through trichlorobenzene to the silicones (> 200 C). Molecular engineering of liquids with greater dielectric strength has not been accomplished, but the synthesis of designed molecules having high-energy storage properties has been very fruitful.

Starting with mineral oil and rosin wax mixtures, the first significant advance was made with the introduction of castor oil, followed by chlorinated naphthalene. The next major advance was the use of pentachlorodiphenyl. Improvements in the uniformity of capacitance of units over large temperature ranges has been the subject of more recent interest and has resulted in the development of the partially fluorinated esters as capacitor impregnants. The trend is shown in Fig. 8.

Dielectrics and the Telecommunications Industry

The second major force affecting dielectric research and the development of new insulants has been the demand for the reliable transmission of intelligence. This became increasingly a subject for study and development by dielectrics experts in the second quarter of this century. The phenomenon, while still that of energy transport, was no longer limited to 60 cycles per second in frequency. In terms of insulants, there

59

were requirements for improved materials for radio-frequency (r-f) and d-c capacitors, r-f transmission cables, and radomes.

Radio-Frequency Capacitors

The communications industry in its first days of growth was interested, so far as capacitors were concerned, with the transmission of high-frequency currents of low voltage. There existed from the beginning, the pedagogue's dream, a capacitor with air as the dielectric which was practically lossless over the frequency and temperature spectrum.

Based on the familiar equation relating capacitance of a parallel plate capacitor directly to area of the plate, and inversely to their separation, mechanical engineers had made strenuous efforts to build air capacitors of high capacitance by bringing the electrodes as close together as possible. Innumerable geometries were proposed to take advantage of this effect, but ultimately it became realized that the dielectric strength of air limited further developments.

While there was a certain flavor of prosperity in large air capacitors, Curtis' classic work on mica capacitors clearly demonstrated the possibility and value of miniaturizing.

With World War II came two problems which required enormous effort to solve: 1. the unavailability of mica suitable for capacitors and 2. the need for high-voltage d-c units with compact efficiency resulted in the development and adaptation of low-loss organic and inorganic materials for capacitors. Thus, polystyrene, polyvinyl carbazole, and polytetrafluorethylene (organic polymers having no permanent electric moments) were fabricated into high-frequency units for band-pass applications. Organic liquids such as mineral oil, silicone oil, and dibutyl sebacate were used in conjunction with parallel plates for resonant tank circuit uses. Meantime, strenuous efforts were made to synthesize bodies which could be fashioned into flakes or continuous sheets. Among the materials which emanated from this work were the fluorophlogopites (synthetic micas) and the low-loss glasses. The results of this effort, therefore, were eminently successful and a gamut of mica substitutes are now available for high-frequency work. This is shown schematically in Fig. 9.

Direct Current

At first the demand for the high-voltage d-c oil-filled unit having nonflammable properties seemed to involve nothing but an adaptation of the a-c pentachlorodiphenyl unit. To everyone's chagrin, it was soon found that this was not true; the units which have life expectancies of 14 to 30 years on alternating current were failing in periods of one week on direct current even when severely derated. The solution came with the establishment of the value of additives such as anthraquinone. Today it is a recognized practice to introduce such additives in insulants (both liquids and solids) for both d-c and a-c applications.

There has always been an enormous interest in low-voltage high-capacitance units having life expectancies as great as those of other components. The electrolytic capacitor, while fabulously successful in storing energy, has been seriously limited by short life times and low operational temperatures. The tantalytic capacitor has made a heartening advance recently in a field in which none was reported in a very long time. For example, there is now available a nonacid electrolytic unit capable of withstanding 125 C for 2,000 hours with a drop in capacitance of only 12%.

Radio Frequency

Just as polar molecules in capacitors caused undue losses to develop, so too the conventional wire and cable coatings were lossy and attenuated a high-frequency signal sent down the transmission line. The demand became eloquent when radar became a necessity and resulted in the rapid wartime development of polyethylene insulated cable. A second such cable employed polystyrene and even polytetrafluorethylene has been used on special projects. Wire and cable coated with polyethylene, which has been cross-linked by ionizing radiation, has also entered the market. The general growth of these items is shown in Fig. 10.

Radomes

Another problem of intelligence transmission which intrigued the dielectrics expert was that of radomes. Here the question was: "How can an antenna transmit and receive radio waves when it is housed inside a protective dome or canopy such as the nose cone or belly of an airplane?" The material must be mechanically strong and not attenuate the signal. As shown in Fig. 11, the materials having the best mechanical properties were ones which underwent maximum dielectric absorption in the r-f range. This led to the serious consideration of dielectric mixtures. In one case glass fiber cloth, the mechanical

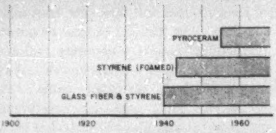

Fig. 12. Radio-frequency radome dielectrics developed because of telecommunication needs

strengthening ingredient, was impregnated with polystyrene, the low-loss dielectric, to yield a canopy. For lower losses, but at the cost of strength, polystyrene foam was used. The most significant advance has been made only recently, however. The material, pyroceram, is an inorganic body of high mechanical and thermal stability and having low electrical losses. The advances are shown in Fig. 12.

Dielectrics and the Automatic Detection and Control Industry

The third force which is making itself felt increasingly may be called automatic detection and control. This entails the development of equipment capable of recognizing a select phenomenon or condition, comparing it with observations previously stored in a memory, and executing a series of prestored commands.

There are, of course, a number of ways of solving these problems without having recourse to dielectrics. For example, light pulses can be monitored by photomultiplier tubes, the number compared with one in a magnetic memory, and the command executed through a conventional servomechanism. Dielectrics enter when a phenomenon associated with the polarization of insulators can be used in one of the three stages. Effects which are being studied include those associated with the Kerr electro-optical effect, ferroelectricity, and electrostriction.

In the case of the detection device it is obvious that the phenomenon to be detected must be a necessary and sufficient condition for developing a signal. Thus, the insulation specialist, using a dielectric phenomenon as the sensing device, must exploit unique changes caused by ambients. The use of capacitance change to detect crevasses at the South Pole is an example of the adaptation of one of the oldest known effects to a present-day problem.

Once established, the search instrument presents the information to that segment of the automatic detection and control instrument called the memory. The basic requirement of any memory is that it be a substance which undergoes a nonlinear change when subjected to a change in ambient.

To the dielectric expert, the switching of a barium titanate crystal from one state of polarization to another by the action of an electric field is an example of how insultants may play a role in automatic detection and control. This is one of the reasons for the widespread interest in the ferroelectrics.

The third problem associated with automatic detection and control involves the execution of a command. The physical movement of charged particles as in xerography, or the elongation of a piece of matter through the action of a electric field, are examples of third stage of automatic detection and control.

While phenomena such as the Kerr electro-optical effect were observed in the last century, the forces motivating research in this field have been sporadic until recently. The work on ferroelectrics is of relatively recent origin even though the piezoelectrics have been studied for a century. In terms of automatic detection and control, Fig. 13 shows the early state of development which now exists.

The Present Status of Dielectric Materials

In summary then, it would appear that at this time there are available a plethora of materials which have been developed to satisfy the requirements of the power industry. While there are certainly improvements to be made, there are available, for use by an engineer, a host of materials from which he may choose. He has a wide range of liquids, solids, and gases available, because in many cases they possess qualities which make them useful in fields other than the electric power industry. Actually, because of this widespread availability, the insulation user finds himself more and more engaged in functionally evaluating the items and from his data deciding which one best suits his needs.

In communications, the atmosphere has changed significantly from the inception of this industry. There are here also an enormous number of materials suggested by their manufacturers for use. Actually, the tremendous nondielectric interest in such things as polyethylene, polystyrene, and teflon have made available to the practicing engineer a continually improving product which he can adapt to his purposes. On the other hand, he is experiencing difficulty in obtaining dielectric materials suited for use in ambients which are certainly not normal. These are the requirements of very high temperatures and exotic radiation environments where telemetry and communications are necessary.

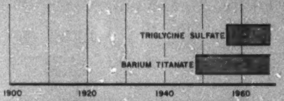

Fig. 13. Ferroelectrics developed because of automatic detection and control needs

Present equipment is designed for use at 85 C, and a definite urge is present to design electronic equipment for 125 C operation. As stop gaps, shielding, cooling, and other protection methods are being used, ceramic tubes are being adapted, and presently available data suggests that their use at 300 C for a short time is feasible now.

In the field of automatic detection and control, the picture is quite different; there are very few materials available to the design engineer, and these are not completely satisfactory. As for such niceties as reliability and stability in exotic environments, these are only in the planning stage.

Anticipated Progress in Insulating Materials

From this analysis an answer to the question of anticipated progress in the field of dielectrics can probably be extrapolated.

The field of power transmission is deeply committed to elucidating the laws of decay of insulation and to determining effects of ambients other than heat on the life expectancy of the items. As a result of such study, the evaluation of old as well as new insulants will become a matter of science. It also seems inevitable that there will appear sporadically new thermally stable enamels, solid insulants, both flexible and rigid, and even new liquids to act as coolants and energy storers.

The revitalization of interest in electrolytic capacitors and their elucidation in terms of solid-state physics will undoubtedly lead to the preparation of new miniaturized capacitors. The capacitance which arises at a *p-n* junction is one such phenomenon likely to be exploited.

The problem in telecommunications which has most significance to dielectric specialists is that of the low electric strength of solids and liquids at high frequencies. In many cases the strength of a gas at radio frequencies is greater than that of the best plastics. Unlike the situation in evaluating the life expectancy of power insulants, there are no theoretical guideposts. It is hoped that the future progress in this field will come from a fundamental knowledge of the mechanism of electric breakdown.

In the field of automatic detection and control extensive new findings can be anticipated in: 1. ferroelectric materials for memories, 2. materials the dielectric properties of which are highly sensitive to changes in ambients, and 3. an increased interest in the exploitation of mechanical-dielectric effects. A mention of ferroelectrics should not suggest that all that is needed are a few quick changes of atoms in the various lattice sites of the perovskite structure, followed by a functional life test program.

Ferroelectrics, unlike ferromagnetics, are per se 2-terminal devices and their properties are far more limited than are those of ferromagnetics. One need only consider the wide variations in magnetic susceptibility, coercivity, and magnetic saturation values and contrast these with the dielectric analog to see this. In fact, even though the ferroelectrics which are being marketed are used mostly in capacitors, the high temperature coefficient, their low electric strength, and low stability on aging suggest that many improvements are required at the materials level.

Many of the uses of such materials are planned for outer-space exploration, but few dielectricians may become involved in developing space ships and rockets. On the other hand, the manufacture of better products and more uniform items will come from developing instruments of control more suited and more apt for the job. The factory problems of today, while apparently mundane in comparison with those faced by the space conquerors, have the same three problems: detection, memory, and control. The judicious adaptation of dielectric effects to quality control offers a fruitful field for exploitation, for it is one of the few where a physical phenomenon has been related so aptly to the chemistry and uniformity of matter.

Let it not be thought that capacitance arrays should be installed on every factory operation. There are probably some being used today which might be removed with impunity. It would seem, however, that if the time-honored principles of dielectrics were re-evaluated in terms of their aptness and unique adaptability to automatic detection and control, improvements in product uniformity would well repay the effort.

◆

Discussion

R. W. Atkinson (General Cable Corporation, Westfield, N. J.): The author shows curves where the abscissa is frequency and goes to the high-megacycle range, the ordinate being called dielectric strength. In the range of the curves, large reduction of the ordinate takes place even for very low-loss material. This large fall-off in the voltage to produce failure is quite surely not dielectric failure in the usual sense. It is rather likely that, because of the increasing loss at the high frequencies observed, the failure is simply a result of heat. There is, in that case, no more reason to speak of dielectric strength than to speak of the dielectric strength of a wire which is melted if a sufficient voltage is placed across the terminals.

If these materials were tested in thin sheets the thermal time constant is quite short and the failure voltage will not be greatly affected by a time period of one minute or less. In any event, tests at the high frequencies and very low volts per mil should not be called tests of dielectric strength or other than a measure of dielectric loss unless this latter has been thoroughly eliminated by adequate analysis, theoretical or experimental.

L. J. Frisco (The Johns Hopkins University, Baltimore, Md.): Mr. Atkinson's remarks concern the author's statements relative to the drastic effect of frequency on the electric strength of solid insulating materials. The breakdown curves which were discussed during the oral presentation of the paper were based on the work of the late J. J. Chapman and his co-workers at the Johns Hopkins University. Data of this type have appeared in several publications.[1–3] Typical data for Teflon (PF), a low-loss material, and asbestos-filled diallyl phthalate (MDAP), a lossy material, are given in Table I.

Mr. Atkinson's remarks certainly apply to a material such as MDAP, which exhibits extremely poor behavior in the r-f range. It will be noted that in addition to a drastic decrease in electric strength, MDAP exhibits changes in the character of failure as the frequency of the applied voltage is increased.

In the case of the low-loss materials, such as PF, the observed decrease in electric strength is not accompanied by a change in the character of failure at the higher frequencies. With these materials, a sharp, pin-point type of puncture is obtained at all frequencies in the range of 60 cps to 100 mc (megacycles) when recessed electrodes are properly applied.[3] Furthermore, only minor variations in electric strength are observed when the breakdown tests are conducted over the temperature range of −55 C to 125 C. Attempts to explain these results on a simple thermal basis have been unsuccessful, a fact which Mr. Atkinson emphasized in his discussion of reference 1.

Other factors which depend upon the total number of cycles of applied voltage over a given test period have also failed to explain the variation of electric strength with increasing frequency. Consequently, the effect must be attributed to time-dependent mechanisms which are associated

Table I. Electric Strength, RMS Volts Per Mil

Frequency	PF	MDAP

with the breakdown process, and in those cases where the character of the breakdown is unaffected by increasing frequency, the measured values of stress must necessarily represent the electric strength of the material. A more complete discussion of the effect of frequency on the electric strength of solids may be found in the text and discussion of reference 1.

Subdivision of Telephone Traffic

IMRE MOLNAR
MEMBER AIEE

TRAFFIC DATA for engineering of telephone switching equipment is usually derived from traffic measurements extended over as large a number of circuit groups and as long periods of observation as practical. The quantities of equipment required in circuit subgroups are then based on the average traffic, prorated to the particular subgroup. The factors governing this averaging process will be analyzed under case I. The converse process, where the total traffic is estimated from observation on a few sample subgroups, is less often used in engineering equipment quantities. In latter instance, Case II, standard methods of statistical estimation are applicable, with additional adjustments which correspond to those discussed herein.

Case I

General Comments

It is important to realize that as telephone traffic is a random phenomenon with great variations in time and among individual sources, data derived from observations during short periods (say individual hours), and from small groups of sources, are useless in engineering. Instead, traffic measurements must be extended over a prolonged period, say many hours, and on many circuits, say over all lines of a central office, or at least over some of its major divisions. Similar consideration applies to the grade of service. For instance, in switching systems where attempts made during congestion are lost, the total attempts lost during prolonged periods of observation should be proportioned to the attempts made or carried during the same period. Whether the grade of service is to be judged for the over-all system or for each subgroup is a matter of definition, and will be discussed later.

However, even where data are obtained over a prolonged period on the over-all system, data of individual subgroups will not agree with an estimate derived by prorating the total system. For instance, the average busy-hour traffic may be originated or received by 10,000 telephone lines; that is, the total traffic measured many days during the hour of highest traffic each of those days, divided by the number of days of measurement. If the 10,000 lines are divided into 100 groups of 100 lines each, and the traffic in each of the 100 groups is measured during the same days but during the hour of heaviest traffic in each group, the average of each group will differ from the average of the first method divided by 100. Furthermore, if the averages of each group are added, the total will be higher than the average of the first method. However, even if the traffic in each group is measured during the hours when the combined traffic of the 10,000 lines is highest, the individual group averages will fluctuate considerably about this prorated over-all average.

There are two reasons for these phenomena. Even though the fact that there are pronounced busy hours in telephone traffic indicates that telephone calls are not placed completely at random, nevertheless the placement of calls by individual sources during certain periods can be considered as practically at random. Each group of sources will develop a busy hour of its own independently from other groups, and only dependent on the prevalent trend of its sources superposed on such random calling. The location of the group busy hours of the several groups will be pseudorandom relative to each other, though with a pronounced trend toward the location of the common office busy hour. This does not preclude the fact that the group busy hours are more pronounced than the office busy hour; on the contrary, these facts are interrelated.

To illustrate this point, consider Fig. 1 in which there are three groups each carrying the same busy-hour traffic, 4 erlangs. The first group has its busy hour between 9:30 and 10:30, the second between 9 and 10, and the third between 10 and 11. To simplify matters, assume that the traffic density (number of occupied devices) remains the same throughout the busy hour, i.e., 4 erlangs; and during the adjacent hours it drops abruptly by 25%, to 3 erlangs, even though, in actual serv-

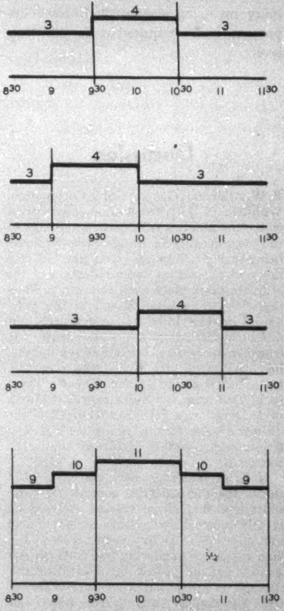

Fig. 1. Busy-hour traffic composition

Paper 57-809 recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting, Montreal, Que., Canada, June 24–28, 1957. Manuscript submitted April 19, 1957; made available for printing October 8, 1958.

Vol.
Pt. 1
1959

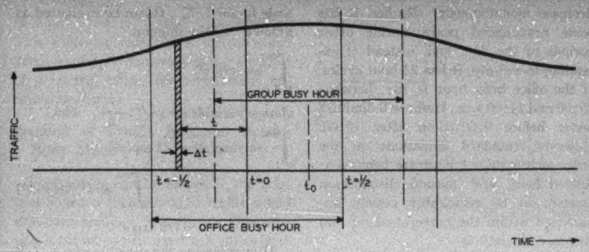

Fig. 2. Traffic density of a certain group in time

ice, the traffic density can be expected to decline gradually on both sides. If the three groups are combined, the over-all busy hour will be between 9:30 and 10:30 with 11 erlangs of traffic, while the sum of the three individual busy hours would be 12 erlangs, or 9% more. The two hours adjacent to the busy hour carry 9.5 erlangs each. The total combined traffic is 30 erlangs, which is, of course, the sum of the traffic in the three groups.

Now, two facts are immediately apparent. First, if the traffic of the combined busy hour is measured and an attempt made to infer from this the traffic of the individual groups, a value of 11/3 =3.67 erlangs is obtained instead of the true value, 4 erlangs; that is, a value which is 9% low. Thus, if one's engineering is based on the prorated average of the combined busy hour, one is caught short during the individual-group busy hour. Second, in the hours adjacent to the over-all busy hour, the combined traffic decreases only about 14%, while the individual-group traffic decreases 25%; therefore, the group busy hour is more pronounced than the over-all busy hour.

In the foregoing example it was assumed that the traffic in each group has the same magnitude, the only difference being the displacement of the busy hours relative to each other. Actually, the individual groups will carry differing amounts of busy-hour traffic, because it is practically impossible to assign to each group traffic sources which would generate exactly the same amount of traffic. Thus even if the busy hours should exactly coincide, the traffic of the individual groups will fluctuate about the prorated average of the combined group. The amount of fluctuation depends on the traffic-generating characteristics of the sources to the several groups with the objective of attaining as close a traffic balance as possible.

Busy-Hour Phase Shift

The phase shift between the busy hours of the subgroups is the more important of the two causes of traffic unbalance. In engineering switching equipment, allowance may be made for this, based on following reasoning.

Consider a large group or a whole central office, consisting of many subgroups each generating the same busy-hour traffic y. The office-busy-hour center point should represent the time $t=0$, while the subgroup-busy-hour center points t_0 are distributed according to some probability function $p(t)$. The traffic density in each subgroup is likewise distributed according to a function $f(t)$, which is assumed to have its maximum value at $t=t_0$, and to be monotonously decreasing and symmetric on both sides of t_0. Furthermore, $f(t)$ is assumed to be the same for all subgroups, except the shift of its crest to t_0. The integral of $f(t)$ between the limits $t_0-1/2$ and $t_0+1/2$ is y, the subgroup busy-hour traffic; while the integral between the limits $t_0+1/2$ and $t_0+3/2$, as well as between $t_0-3/2$ and $t_0-1/2$, is y', the subgroup adjacent-to-the-busy-hour traffic.

In Fig. 2 the function $f(t)$ of a certain group is shown, centered around its particular t_0. During a brief interval Δt at an arbitrary time t in the office busy hour, this group will generate traffic $f(t-t_0)t$; therefore the total traffic of the group during the office busy hour will be

$$\int_{-1/2}^{+1/2} f(t-t_0)dt$$

Assuming again that the function $f(t)$ is the same for all groups, the value of the group traffic during the office busy hour will depend on the location of t_0. As has been shown, t_0 varies according to a probability function $p(t_0)$, so the traffic expected in an arbitrary *group* during the *office* busy hour will be

$$\int p(t_0)dt_0 \int_{-1/2}^{+1/2} f(t-t_0)dt \qquad (1)$$

The limits of the first integral depend on how far the group busy hours stray from the office busy hour. They will, of course, in any case be contained within a 24-hour period. Ordinarily, for traffic groupings of practical interest, almost all group busy hours remain within less than 2 hours on either side of $t=0$ and therefore little error will be incurred by extending the limits of integration to infinity.

To solve equation 1 the traffic distribution $f(t)$ of a subgroup should be known. According to statistical evidence, the decline of the group busy-hour traffic to adjacent hours is gradual. If the group busy-hour traffic is y, and the traffic during the hour on each side is y', the decline is about 35% for 1-erlang traffic, 15% for 10 erlangs, and 12% for 100 erlangs. To simplify evaluation of equation 1, assume that during the group busy hour $f(t)$ has a constant value y, and it then drops abruptly to y'. There is also evidence that the decline of traffic during the second hour away from the busy hour is even less, and as its influence on the office busy-hour traffic is small anyhow, assume that everywhere outside the

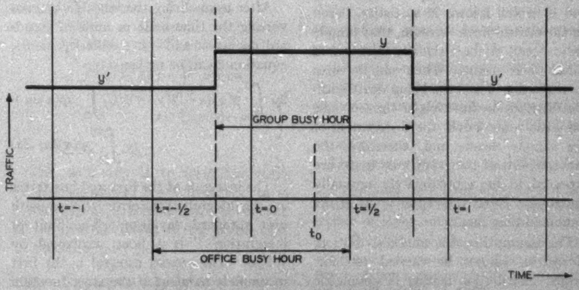

Fig. 3. Relation of office to group busy hour

group busy hour $f(t)$ remains constant, y'.

From these considerations and from Fig. 3, estimate the contribution of a group to the office busy-hour traffic as $y(1-t_0)+y't_0$ when $-1<t_0<+1$, and y' when t_0 lies beyond. The traffic expected in the group during the office busy hour will therefore be

$$\int_0^1 p(t)2y(1-t)dt+\int_0^1 p(t)2y'tdt+\int_1^{\mathrm{inf}} p(t)2y'dt \quad (2)$$

To solve equation 2 one must also know the probability distribution of the group-busy-hour location $p(t)$. From statistical evidence it appears that in local telephone traffic the group-busy-hour center points are approximately normally distributed about the office-busy-hour center point, with a standard deviation of s hour. Therefore, one hour is $1/s$ standard deviations.

There is also some theoretical justification for the normal distribution of the group-busy-hour center points. Consider again a central office consisting of 100 groups of 100 lines each. Each of the 10,000 lines is used at random, or at least according to some frequency function about which little is known. These 10,000 lines form a universe, from which 100 samples are picked in sets of 100 lines each. (Although irrelevant for this illustration, it is assumed that each 100-line sample originates the same traffic volume.) It may likewise be supposed that there is a "busy hour" for every line, also according to some frequency distribution over the universe, of which, also, little is known. The center points of the busy hour of each of the sample groups are the mean values created by the individual-line busy hours within the group, and the center point of the office busy hour is a mean value created by the distribution of the center points of the group busy hours. These group busy hours are distributed according to some frequency function, and it is well known in statistics, based on the central limit theorem, that sample means tend to be normally distributed about their mean. When sample sizes on the order of 100 are being dealt with, the distribution function of the universe has little control over the distribution of the sample means and, therefore, the center points of the group busy hours are expected to be approximately normally distributed about the center point of the combined busy hour.

The assumption of normal distribution, of course, cannot be carried too far. Traffic distribution neither is symmetric about the office busy hour, nor does it decrease monotonously. Rather, it has some pronounced peaks during other periods of the day, and, instead of extending to infinity, it has 24-hour cycles. If the office busy hour is, say, between 10:00 and 11:00 a.m., traffic will diminish faster before 9:00 than after 12:00. However, standard deviations on the order of less than 1 hour are being considered here, and normal distribution appears to be reasonably closely approached within the range of about two standard deviations.

The value of the standard deviation s is obviously a function of the traffic: If the groups handle large traffic volumes, their busy hours will be clustered more closely together than would be the busy hours of groups with less traffic. Consider a population consisting of the center points t_0 of the group busy hours. According to the previous assumptions, each group carries the same traffic y, and t_0 has a Gaussian distribution with a mean value 0 and variance s^2, where $s=s(y)$. A large number of sample groups, say 100, are now chosen from the population. The sample means can be expected to be near 0, the sample standard deviation close to s, and the sample distribution to be normal. A second sample of 100 groups is now taken, and by random addition of the two samples a new sample of 100 groups is obtained, each carrying $2y$ erlangs of traffic. The mean of the new sample will be near 0, the standard deviation near $s/\sqrt{2}$, and again the distribution will be normal. Similarly, combining n sets of sample groups will yield a new set of sample groups carrying a traffic of ny erlangs, with mean value 0 and standard deviation $s(ny)=s(y)/\sqrt{n}$. The only assumptions made were: 1. a normally distributed population of a very large number of groups each carrying the same traffic, and 2. a very large number of sample groups, yielding a large number of samples even after n groups were combined.

After normalizing the variable by converting the time scale in units of standard deviation and other rearrangements, equation 2 can be replaced by

$$2y\int_0^T p(u)du-[2(y-y')/T]\int_0^T up(u)du+2y'\int_T^{\mathrm{inf}} p(u)du \quad (3)$$

The integrals of the first and last terms are the integrals of the error function, with unit standard deviation. The limit of integration T is 1 hour, expressed by $1/s(y)$. The second integral is the first incomplete moment of the error function from 0 to T standard deviations, with a scale factor $1/T$. It can be evaluated as follows. In the integral

$$\int_x^{\mathrm{inf}} vdv/\exp(v^2)$$

change variable $v=x\sqrt{(1+r)}$. Thus

$$\int_x^{\mathrm{inf}} vdv/\exp(v^2)=1/2\exp(x^2)\int_0^{\mathrm{inf}} d(rx^2)/\exp(rx^2)=1/2\exp(x^2)$$

After replacing the variable v by $u/\sqrt{2}$ and multiplying both sides by $1/\sqrt{(2\pi)}$, the right side becomes the error function with unit standard deviation $p(u)$, thus

$$\int_0^T up(u)du=p(0)-p(T) \quad (4)$$

Designating

$$2\left(\int_0^T p(u)du-(1/T)\int_0^T up(u)du\right)=2\left(\int_0^T p(u)du-(1/T)[p(0)-p(T)]\right)$$

by A, equation 3 becomes

$$Ay+(1-A)y'$$

The last expression represents the contribution of a subgroup to the office busy-hour traffic, when the subgroup busy-hour traffic is y and the subgroup traffic adjacent to the busy hour is y'. If the combined traffic of all n subgroups during the office busy hour is Y, the prorated amount applicable to one subgroup is

$$Y/n=Ay+(1-A)y' \quad (5)$$

In the usual case Y is known from estimate or measurement, and y can be calculated by increasing Y/n by the percentage

$$a=100(y-Y/n)/(Y/n) \quad (6)$$

If, however, the subgroup busy-hour traffic y is known and its contribution to the combined busy hour is to be estimated, y should be decreased by the percentage

$$a_1=100(y-Y/n)/y \quad (7)$$

Then a and a_1 can be tabulated against Y/n and y, respectively, or instead, corresponding values of Y/n and y can be shown. Above about 2 or 3 erlangs an interchange of a and a_1 is within engineering accuracy.

Obviously, the closer y' approaches y (which actually it does when traffic increases), the smaller adjustment a is required. In the trivial case $y'=y$, equation 6 gives $Y/n=y$, as it should, because when the traffic volume embraces a large proportion of the total traffic

(n approaches 1), Y also approaches y. This conforms with the experience that when a group embraces a major division of a central office, the adjustment becomes negligible.

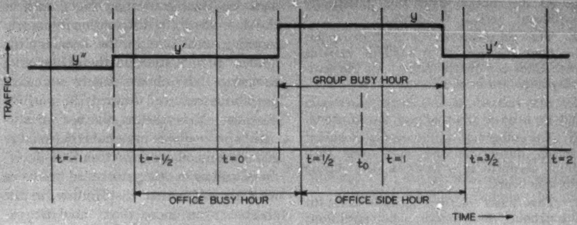

Fig. 4. Relation between busy hour and side hours

Decline of Traffic Adjacent to the Busy Hour

Equation 5 can be solved if the relation between the busy-hour traffic y and side-hour traffic y' is known. This relation is not inherently fixed, but varies from case to case, and, in particular, it will depend on the amount of traffic y, as already implied. The decline becomes less pronounced with increasing traffic. For any specific application, the relation between y and y' can be established reliably only by a traffic study. However, a general idea can be obtained by considerations similar to those in the preceding section.

Assume again that the traffic in the side hours of a large group is generated by its subgroups. The contributions of the subgroups are again shifted in phase, just as were their contributions to the over-all busy hour. And, although the exact amount really is not very important, assume that subgroup traffic 2 hours removed from the subgroup busy hour declines from y' to $y''=y'(1+y'/y)/2$.

Fig. 4 illustrates this case, except that for simplification the second decline just referred to will be considered only when t_0 is less than 0. When t_0 is above $t=2$, its effect is insignificant. The traffic each group contributes in the hour adjacent to the over-all busy hour is

y'' if $t_0<-1$

$y'(t_0+1)-y''t_0$ if $-1<t_0<0$

$yt_0+y'(1-t_0)$ if $0<t_0<1$

$y(2-t_0)+y'(t_0-1)$ if $1<t_0<2$

y' if $2<t_0$

where t_0 is again the center point of the group busy hour and $t=0$ is the center point of the over-all busy hour. The expected contribution of a group to the traffic of the side hour is, therefore,

$$y''\int_{-\inf}^{-1}p(t)dt+(y'-y'')\int_{-1}^{0}tp(t)dt+ y'\int_{-1}^{0}p(t)dt+(y-y')\int_{0}^{1}tp(t)dt+ y'\int_{0}^{1}p(t)dt+(2y-y')\int_{1}^{2}p(t)dt- (y-y')\int_{1}^{2}tp(t)dt+y'\int_{2}^{\inf}p(t)dt$$

$$=y'(1+y'/y)/2\left(1/2-\int_0^1 p(t)dt+\int_0^1 tp(t)dt\right)+(y-2y')\int_0^1 tp(t)dt+ 2y'\int_0^1 p(t)dt+(2y-y')\int_1^2 p(t)dt- (y-y')\int_1^2 tp(t)dt+y'\int_2^{\inf}p(t)dt \quad (8)$$

The frequency function $p(t)$ will be that used in the preceding section, with the same variance $s(y)^2$. Therefore, after normalizing equation 8 by a change of variable, the following is obtained:

$$y\Bigg(2\int_T^{2T}p(u)du+\Bigg[(1/T)\Bigg(\int_0^T up(u)du-\int_T^{2T}up(u)du\Bigg)\Bigg]+y'\Bigg[2\int_0^T p(u)du-\int_T^{2T}p(u)du+\int_{2T}^{\inf}p(u)du+(1/T)\times\Bigg(\int_T^{2T}up(u)du-2\int_0^T up(u)du\Bigg]+(1+y'/y)/2\Bigg[1/2-\int_0^T p(u)du+(1/T)\int_0^T up(u)du\Bigg] \quad (9)$$

After a few rearrangements, equation 9 can be expressed as

$$Y'/n=Cy+Dy' \quad (10)$$

where

$$C=2\int_0^{2T}p(u)du-2\int_0^T p(u)du+(1/T)[p(0)-2p(T)+p(2T)]$$

$$D=1/2+\int_0^T p(u)du-2\int_0^{2T}p(u)du-(1/T)[2p(0)+p(2T)-3p(T)]+(1+y'/y)/2\left\{1/2-\int_0^T p(u)du+(1/T)[p(0)-p(T)]\right\}$$

$$=1-C-E$$

The next step is to form the ratio $(Y/n)/(Y'/n)=Y/Y'=k$ from equations 5 and 10, as a measure of the decline of the over-all traffic in the hours next to the office busy hour

$$Y/Y'=\Big(Ay+\Big(1-A\Big)y'\Big)\Big/(Cy+(1-C-E)y')=k$$

where

$$E=(1+y'/y)/2\left\{1/2-\int_0^T p(u)du+(1/T)[p(0)-p(T)]\right\}$$

and

$$y'=y/(1+[k(1-E)-1]/(A-kC) \quad (11)$$

The ratio y'/y needed for E can be estimated by successive approximation by first assuming E to be zero and computing y' for a few selected values of k. The next step usually provides a sufficiently close value of E. As the parameters A and C and E are tabulated functions of the normal distribution and depend on y only through $T=1/s(y)$, they can readily be computed before y' is known. Parameter k may be considered a constant of a given universe of line groups, say for a certain central office, when it is the ratio of the office busy-hour traffic to its adjacent-hour traffic.

Review of the Conditions

Before proceeding with the numerical evaluation of the results, the basic assumptions will be reviewed. It may also be of interest to note that the preceding discussions did not employ the usual paraphernalia of telephone traffic problems: statistical equilibrium, holding-time distributions, Poisson process, congestion theory, etc. Instead, the following few assumptions were made as to the gross statistical distribution of the traffic over a period of several hours, and then the results were obtained directly by the elementary analytic methods of sampling, using only the extensively tabulated error function.

The assumptions were as follows:

1. The traffic of a large unit, for instance of a large central office, is the sum of the traffics of many subgroups of the unit.
2. The traffic of the unit as well as the subgroups, integrated over 1-hour periods, has a definite maximum in a prolonged period, say within 24 hours.
3. The traffic of every subgroup, as well

as its distribution over the statistically significant period, is identical.

4. The subgroup-busy-hour center-point locations conform to a random variable with Gaussian distribution about the unit-busy-hour center point.

5. The variance of this distribution is in inverse ratio to the traffic of the subgroup.

6. The subgroup traffic has a constant density during its busy hour, and then drops abruptly to a lesser density during the side hours.

7. This lesser density remains constant throughout the statistically significant range of the side hours.

8. The population of subgroups contains a sufficiently large number of subgroups so that the results will be asymptotically exact.

Granting the foregoing assumptions, there remains only to specify two parameters for the numerical evaluation: the variance of the distribution, and the ratio of the traffic in the busy hour to the traffic in the side hours. Neither of these two has inherently universal properties, nor are there any probability considerations to be of help. They will vary between individual applications; from a traffic study for each case, they should preferably be established by statistical methods. Traffic characteristics of a central office serving predominantly business establishments differ from those of a central office serving only residences. Traffic characteristics of a college town differ from those of a seaport. Paystation groups have their own peculiar traffic distribution. Toll traffic has different characteristics from local traffic. Individual toll-circuit groups have pronouncedly separated busy hours, particularly where the terminals are in different time zones. With such diverse conditions it would seem impossible to construct universally applicable adjustment factors for subgroupings. However, there are enough applications of generally similar characteristics to permit the computation of an average set of adjustment factors, sufficiently close for engineering use where proper statistical data are not available. The usual adjustment rarely exceeds 10% to 15%, and if adjustments are applied conservatively, second-order accuracy is not warranted. It is more important to be conscious of the need of an adjustment and to apply the approximate amount, than to seek dubious precision.

Assumption 1 is self-evident, and assumption 2 is an established fact. Assumption 3 is a temporary expedient which was used to appraise the contribution of the busy-hour phase shift, and will be dropped in later sections. Theoretic justification of assumption 4 has already been attempted, in spite of some undeniable contrary facts, such as the skewness of the distribution from early morning until late in the evening, the 24-hour periodicity, and the existence of subgroup busy hours many standard deviations removed toward the positive abscissa. Nevertheless, the test for normality on available material is reasonably good within about two standard deviations, and as in other statistical processes with a quasi-normal distribution, in the absence of a more exact analytic expression, the error function yields satisfactory results for engineering purposes. Actually, the subgroup busy hours will usually be contained within about a 4-hour period during the morning, and the number of those which fall beyond are fewer than what should be contained in the tails of the normal distribution. Therefore, the theoretic adjustment factor a is somewhat overestimated, which will tend to compensate for the errors due to assumptions 6 and 7.

Theoretical justification has also been attempted for assumption 5, but its statistical verification is rather difficult because it requires substantial data covering a wide range of subgroup traffic values, and the available measuring technique is complex and tedious. The best that can be said is that the scant material available to the author does not refute the assumption. This uncertainty is unfortunate, and because of the two parameters the standard deviation is the more decisive on the shape of the functional relation between traffic and adjustment a. When the standard deviation is small, the integration over the office busy hour will include practically all subgroup busy hours, and equation 5 factor A will approach unity rapidly with increasing subgroup traffic y on two accounts: more rapid convergence of the error integral, and the scale factor $1/T$. Side-hour traffic y' will have a diminishing importance, and the need for adjustment a will disappear at relatively low subgroup traffic volumes. Conversely, when the standard deviation is large, the side-hour traffic will exert more influence, and larger adjustments a are required.

It has been seen that if the standard deviation $s(y_1)$ for a certain traffic y_1 is known, then the standard deviation for traffic value y is $s(y)=s(y_1)/\sqrt{(y/y_1)}$. If one knows the value $s(y_1)\sqrt{y_1}=1/r$ from a certain set of observations, $s(y)$ can be determined for any value of y from assumption 5 as $s(y)=1/r\sqrt{y}$, provided that y and y_1 belong to sets of samples of the same normally distributed population, and that $s(y_1)$ is a satisfactory estimate for the standard deviation of the population. Then parameter T of the error function is

$$T=1/s(y)=r\sqrt{y} \tag{12}$$

The value r should preferably be determined from a study of the distribution of the center points of a large number of group busy hours in some typical applications with relatively small values of traffic, such as on 100 or more groups of 100 lines each within a central office. Even though the values of r obtained this way may not have universal validity, the average from a sufficient number of studies will permit the construction of a curve $a=f(Y/n)$, which if judiciously applied should be satisfactory.

From studies the author has made on the terminating-traffic distribution of large central offices, as well as from material available elsewhere in the literature, it appears that for subgroup traffic on the order of 2 to 2.5 erlangs the standard deviation may vary between 0.55 and 0.65 hour, with a range for r between 1.2 and 1.0 if the traffic is expressed in erlangs. Conservatively, 1.0 was chosen for the computations in the present study. For different traffic characteristics, for instance in toll traffic where local time differences increase the standard deviation, the adjustment factors a which are suggested here may need to be slightly increased.

Assumption 6 is obviously contrary to the facts, since the traffic density shows a marked decline in both directions already during the busy hour, with a gradual transition toward the side hours. Nevertheless, the assumption is tenable, for any better interpolation would unduly complicate the computations without sufficiently increasing the accuracy of our result. Assumption 6 slightly overemphasizes the contributions of the group busy hours near the office busy hour, and these hours carry more weight due to the characteristic of the error function $p(u)$. Therefore, the value of a is slightly underestimated but the error is small compared with the uncertainty already present in the choice of r. The error is greater when the difference between y and y' is greater, that is, for small values of y. By the choice of a low value for r and, as will be shown later, by the character of the ratio y/y', such errors are already sufficiently compensated.

Assumption 7 is likewise contrary to the facts, since the traffic density declines steadily during the side hours, at least within a range of several hours. Here, again, the assumption simplifies computations without markedly debasing the accuracy. The error is due to extension of the integration over the last term in equation 3 to infinity, instead of only to $2T$, plus successive terms with steadily diminishing traffic values. Now, for traffic values above about 1 erlang the difference between the integral to infinity and to $2T$ is less than 2%. But since this integral even at 1 erlang only represents about one third of the value of equation 3, the use of y' over the tails of the distribution instead of a, say, 20% to 30% lesser value, would only reduce the value of equation 3 by a fraction of 1% at 1 erlang, and would be completely insignificant at higher traffic values. In general this error will likewise tend to underestimate the adjustment factor a.

Assumption 6 would also tend to give a somewhat high value for y', due to equation 8, which again is insignificant when the traffic is not too small. Small values $(y-y')/y$ tend to reduce adjustment a, but since it has only a second-order effect, and even for low traffic values the error is small anyhow, a conservative choice of the parameters will compensate adequately. The errors incurred by assumption 7 in the computation of y' were for all practical purposes compensated by the term E.

Assumption 8 has not been explicitly stated in the derivation of the equations; however, its oversight may lead to paradoxical results. For instance, consider a central office consisting of 100 subgroups of 100 lines each, with a total busy-hour traffic of 250 erlangs. The prorated traffic per subgroup is 2.5 erlangs, and if say, a 12% adjustment is applied, the subgroup busy hour will be 2.8 erlangs. If the theory is correct, traffic measurement should confirm it. Now, instead, take the same 10,000 lines and divide the office into ten groups of 1,000 lines each, with a prorated traffic of 25 erlangs per group. The correct adjustment for such a group is 2%, and the group busy-hour traffic will be 25.5 erlangs. If in the next step only one of these 1,000-line groups is considered out of context with the central office of which it is only a part, and it is divided into ten subgroups of 100 lines each, the prorated traffic per subgroup is 2.55 erlangs. Applying the same approximate correcting factor used previously (12%), the subgroup busy-hour traffic should be now 2.86 erlangs instead of the previous 2.8 erlangs. Obviously the subgroups remained the same, and thus a dilemma arises.

The answer is in assumption 8. In integrating the distribution function as well as in deriving equation 12, an infinite population of normally distributed subgroups was assumed, and the expression obtained for adjustment a is an asymptotic one with the proviso that in the subdivision Y/n, n is a very large quantity, which means that a large volume of traffic was subdivided into many components. When the central office was subdivided into 100 subgroups, 2.8 erlangs were obtained in each, in accordance with the hypothesis. However, when the central office is divided into ten groups, these will not carry equal amounts of traffic in their group busy hours, but will have a distribution similar to a set of ten random samples of ten random items each from the population of the subgroups. Now it is known from an exact sampling theory that in the distribution of samples containing only a few items the expected standard deviation of the samples is less than the standard deviation of the population. For instance, in samples containing only ten items of a Gaussian population the expected standard deviation is about 7% less than the standard deviation of the population. It has been shown that the adjustment a required for subgrouping diminishes with decreasing standard deviation. There are exact sampling theories available in statistics where the sample sizes are taken into consideration for the estimation of the parameters in a distribution. Indeed, it can be shown by more detailed analysis that adjustment a becomes less when the overall traffic is divided into fewer components; that is, the smaller n is in Y/n. The construction of charts with n as parameter, as well as their use, becomes unduly involved, and the accuracy of the asymptotic approach suffices for all practical purposes.

However, in engineering subdivided traffic, it is advisable to consider whether the traffic which is to be divided embraces a whole population, or is only a sample of the population and whether as such has been derived already by a process of subdivision. In the latter case, and referring again to the previous example, the 25.5 erlangs, which were assumed to be the group busy-hour average traffic, should have been reduced to the office busy-hour traffic of 25 erlangs before further division into ten subgroups each.

Computation of the Correcting Factor

The last step is to assign a value to the parameter k in equation 11. As will be recalled, if k is known, the traffic y' in the hours next to the subgroup busy hour can be computed, based on assumption 8. The constant k is the ratio of the office busy-hour traffic Y to its adjacent-hour traffic Y', and, of course, will vary in different applications. The problem again is to choose a value which would fit most of the important cases. Obviously the higher the value of k, the greater the spread between the busy hour and the side hours, and the greater adjustment a is necessary. Fortunately, the office busy-hour traffic values Y and Y' are comparatively simple to determine from the traffic volumes of large central offices, and $k=1.12$ appears to be a suitable value. The per-cent decline of traffic $b=100(y-Y')/y$ from the busy hour to the side hours is plotted with $k=1.12$ in Fig. 5.

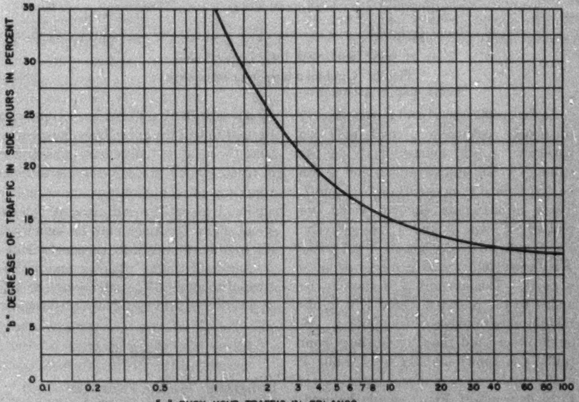

Fig. 5. Per-cent decline of traffic from busy hour to side hours

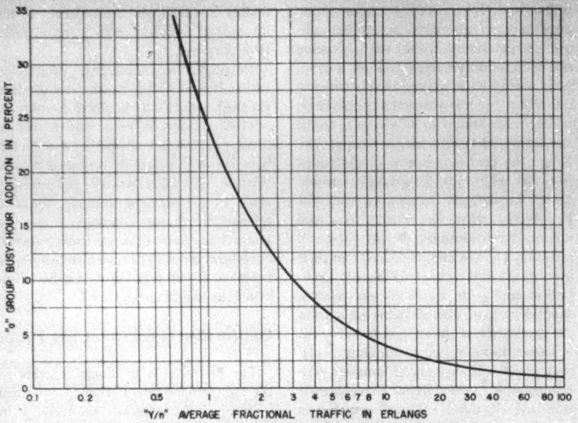

Fig. 6. "Y/n" subgroup busy-hour traffic adjustment

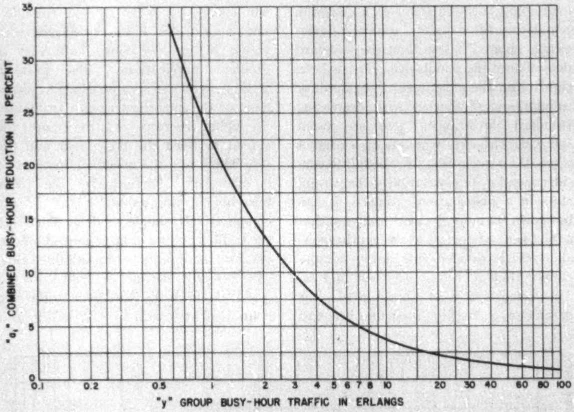

Fig. 7. Combined busy-hour adjustment

As the coefficients A and C were already previously calculable, based only on parameter r and independently of the value of k, the adjustments a and a_1 can be determined from equations 5, 6, and 7. These adjustments (in per cent) are plotted in Figs. 6 and 7, respectively. Fig. 6 is to be used when the total traffic Y is known, and it is to be subdivided into n parts. The amount a is then to be added to the prorated traffic Y/n to obtain the subgroup busy-hour traffic y. If, on the other hand, the subgroup busy-hour traffic y is known and the total traffic Y of the combination of n such subgroups is to be determined, Fig. 7 should be used. The adjustment a_1 is to be subtracted now from y and the remainder multiplied by n to obtain Y. These figures may also be used to find the group busy-hour traffic from the measured office busy-hour traffic of trunk groups or vice versa, for tandem trunking, alternate routing, and similar applications. The adjustment above about $Y/n=5$ erlangs may be somewhat low in some applications, such as for long-distance toll traffic, where it may be increased to about 6% at 10 erlangs, to 4% at 20 erlangs, and to 2% at 50 erlangs.

Case II

Subgroup Traffic Variation

The discussion of Case I explains the general busy hour in a telephone office as a synthesis of many individual subgroup busy hours shifted in phase relative to each other. With the adjustments specified in Figs. 6 and 7, the busy-hour traffic of a *subgroup* can be estimated if its *parent-group* busy-hour traffic is known, or conversely. This is very useful in many applications where such individual information is available.

In the majority of applications for local switching, however, only the over-all office busy-hour traffic Y may be available, and in this case the individual subgroup traffic can be estimated by Fig. 6 only if, according to assumption 3, all subgroups carry equal traffic. Now, such even subdivision of traffic is attainable only in special applications, such as in an automatic call-distribution system to a team of operators where the work-time of calls is approximately equal, but in such case not even a phase-shift adjustment is permissible. In more common applications, however, even subdivision is impossible. There are cases where it is inherently impossible, such as when a large amount of traffic is to be split into several unequal trunk groups. There are other cases where equalization has great practical difficulties, for instance when the bulk terminating traffic in an office is to be channeled to, say, 100 connector groups of 100 terminals each. In the administration of number assignments great care usually is taken to select the traffic characteristics of individual customers with the object of traffic equalization between the connector groups, and, to some degree, the success depends on the effort devoted to the selection. But no matter how perfect the administration is, there is a limit, because characteristics change in time, particularly when vacated terminals must immediately be reassigned, and also because number changes are to be avoided.

From what has been said it is apparent that in the first case, the varying sized trunk groups, each group must be individually appraised, preferably by individual traffic measurements. In the second case, the connector grouping, only an average estimate of the variation can be made, which may be too high or too low, depending on the effectiveness of the terminal assignment in the particular application.

If the subgroup traffics vary about their average, it may not be correct to apply the average adjustment associated with the average subgroup traffic. Fig. 7 shows that the adjustment decreases with increasing traffic, but if drawn on a linear scale, the rate of change is reasonably constant within a moderate range, and it

Vol.
Pt. 1
1959

likewise decreases with increasing traffic. This means that if the variation of subgroup traffic is moderate and symmetric about the average, it is satisfactory to work with the average adjustment. Actually the variation of traffic is such that the groups with lower-than-average traffic are clustered closer to the mean, while those with higher-than-average traffic stray farther away, which will tend to compensate for the decreasing slope of the adjustment.

These relations can also be considered through equation 5, where $Y/n=yA+y'(1-A)$. Of interest here is the constancy of $d(Y/n)/dy=(y-y')\,dA/dy+(1-A)dy'/dy+A$ within a reasonable range or that the second derivative $2dA/dy-(y'+dA/dy)(dy'/dy)+(y-y')(d^2A/dy^2)+(1-A)(d^2y'/dy^2)$ should be insignificantly small. These can be verified by inspection of the second differences and also by intuition: in $d(Y/n)/dy$ the first factor of the first term increases with increasing y, the second factor decreases probably to a somewhat lesser degree, both factors in the second term decrease, and the third term increases about the same degree as the second factor in the second term decreases. Thus it can be expected that the whole expression tends to be constant within a moderate range. Indeed, three rather extreme cases with 100 subgroups may be calculated: in the first, all 100 groups carry the same traffic $y=2$ erlangs; in the second, 50 groups carry 2 erlangs each, and two sets of 25 groups each carry 1 and 3 erlangs respectively; in the third, 60 groups carry 2 erlangs each, 30 groups 1.5 erlangs each, and 10 groups 3.5 erlangs each; and the results of the three will be indistinguishable. As a matter of fact, one more case can be calculated: 50 groups carry 1 erlang traffic each, and 50 others carry 3 erlangs each; the result will be only about 1/2% higher than the previous three, which is insignificant when one considers the accuracy with which the graphs can be read.

The Grade-of-Service Objectives

Apparently assumption 3 may be dispensed with since Figs. 5, 6, and 7 give the information necessary to estimate group busy-hour traffics, office busy-hour traffics, and side-hour traffics, subject, of course, to the validity of the other assumptions and the propriety of the empirical parameters r and k. Under these conditions it should be possible to obtain the expectation of the traffic by statistical methods.

However, traffic data are only the means to estimate the amount of equipment needed, and the equipment is only the means to provide service to the user. As in all branches of engineering, it is useless to attempt to specify equipment for a certain demand unless the service to be given is also considered. But it is interesting to note that while the demand (in this case the traffic) is something real and the equipment, of course, something very tangible, the service, on the other hand, is something elusive. It is a simple matter to express the grade service in concrete terms, and to construct a mathematic model or measuring means to verify whether this grade of service is satisfied or not by the equipment in any one situation. But one is confronted with great obscurity if he tries to find out by an objective measure what grade of service is the correct one for the specific type of service as far as the user of the service is concerned.

How is the grade of service in telephone traffic established? One may take a scientific approach, based on the fact that improved service creates an increasing volume of business, and continue to improve service until the point of diminishing return is reached when the cost of improvement is greater than the incremental revenue it creates. Or one may say that the service is to be given that the customer demands, but then he is on very uncertain grounds. The customer's reaction is very different depending whether he is in a situation where he has to put up with poor service regardless how much he complains, or where his complaints are heeded even though generally the service is considered satisfactory. To a large extent the grade of service is established by tradition based on the conditions prevailing in a particular service industry and to which the public became accustomed. A person may continue to patronize a transportation line, but would flood the Public Service Commission with complaints if a similar grade of service would be given by the telephone company. He may do business with a telephone order house or a ticket reservation office, but would not tolerate the same delay in answer by a toll operator. Many of the accepted grades of service were established by individual judgment, sometimes just intuitively or even emotionally, but once they entered the public domain they tend to perpetuate themselves—with a trend toward continual improvement.

In general, the grade of service provided by telephone systems is among the highest in any industry, and it appears to be sound, judging from their phenomenal growth and the satisfactory return on the investment at reasonable rates.

The purpose of the foregoing digression is to make it clear that there is nothing objective behind the apparent exactitude of the grade of service or the various congestion theories. Their purpose is to establish a common measure for the comparison of service results, and nothing more. The choice of one or another grade of service must be made on considerations unrelated to the mathematic problems of switching and congestion. The grade-of-service objective may be expressed in an almost unlimited variety of ways, of which the following are typical:

1. In a set of subgroups, the grade of service given to the subgroup with highest traffic during its average busy hour should not be worse than the specified amount.
2. In a set of subgroups, the average grade of service given to all subgroups in a switching rank during their respective busy hours should not be worse than the specified amount.
3. In a set of subgroups, the average grade of service given to all subgroups in a switching rank during a specified period, say over 24 hours of the average business day, should not be worse than the specified amount.
4. For a central office, the grade of service given by a switching rank to the combined traffic during the average office busy hour should not be worse than the specified amount.

Requirement 1 is obviously extravagant. With the usual variations among subgroups there are only very few whose traffic exceeds the average by, say, 30%, and to take care of these few may mean a general increase in cost of perhaps nearly 30%. Requirement 2 has a bearing on the subgrouping adjustment and will be discussed first in some detail, with the other specifications to be taken up afterward.

Behavior of the Loss

If objective 2 is accepted, one can expect that subgroups which carry more-than-average traffic during their subgroup busy hours will have a poorer than average, while those with lower-than-average traffic will have a better-than-average grade of service, but the grade of service for the totality of subgroups will be the specified amount. For the time being, consider only the grade of service in a single switching rank. As a measure for the grade of service take the amount of attempted traffic "lost" because of insufficient number of trunks, and calculate it according to Erlang's theory. The latter choice was made as a matter of convenience, since the result would not be noticeably different by any other of the accepted theories. For the present purpose, one may also disregard subtleties in definitions applied to Erlang's theory.

Assume then that an office with 100 groups carries traffic $y=220$ erlangs, so $Y/n=2.2$, and with $a=13\%$, the traffic per group is about 2.5 erlangs. Specify a grade of service $P=0.01$, and for $y=2.5$ at $P=0.009983$ Erlang's theory specifies $N=7$ trunks. Assume also that the maximum group busy-hour traffic observed in any of the groups is 3.7 erlangs, and the minimum is 1.7 erlangs. If seven trunks each are assigned to all groups, in the 3.7-erlang group they will give a grade of service $P=0.048270$, and in the 1.7-erlang group $P=0.001488$. These two average $P=0.024879$, that is, 2.5 times the objective. The reason for this is that loss equations are highly nonlinear. Loss increases steeply with increasing traffic, so the average loss will be considerably higher than the loss computed for the average traffic.

Based on specification 2, the groups with high traffic will suffer higher losses and those with small traffic, lower losses, but the objective here is to keep the average loss to 1%, which means that the sum of all individual-group losses should be 1% of the sum of all individual-group busy-hour traffics, or 2.5 erlangs. To accomplish this, the number of trunks must be increased to more than seven. To include the effect of group variation in the congestion equation is impractical. Instead, the average group busy-hour traffic figure can be increased enough to obtain from the standard tables the correct number of trunks yielding the specified loss. This proposed second adjustment c is in a way fictitious. A real increase in traffic over y does not take place, and therefore is not measurable. Its only purpose is to compute the number of trunks required to satisfy specification 2.

Variation in Subgroup Traffic

To obtain adjustment c, one must know the characteristics of the subgroup traffic variations. As already mentioned, there is nothing inherently fixed in these variations, but they change from situation to situation, dependent on the success in the traffic-equalization attempt. The traffic a large-city local central-office unit switched to 95 groups of stations, with an average of about 96 stations per group, was studied for a year. This particular central office was chosen because the character of the stations was well balanced between business lines, residential lines, individual lines, party lines, and pay-station lines, and the administration of load assignment was somewhat better than average, and also because during the period of the study there was less than ±0.4% change in the number of stations connected to the unit. While the administration may have been better than average, there is little choice in subsequent reassignments in an office over 10 years in service and filled to capacity. Furthermore, due to the reluctance for number changes, unbalance is quite pronounced in terminating traffic while in originating primary groups the degree of load balance depends on the effort devoted to line rearrangements. The average number of calls received per station in the group busy hours was 0.59, and the average group busy-hour traffic per group was 2.572 erlangs with 0.382-erlang standard deviation. The characteristics of larger traffic values were obtained readily by random combination of the subgroups. Other studies of lesser scope, and also evaluation of material found in the literature, confirmed that the conclusions derived from these studies can be generalized for the average application. There are some common characteristics in all these distributions. For instance, it appears that the standard deviation of the distribution of subgroup busy-hour traffic varies within the range of $\sqrt{y}/3.5$ to $\sqrt{y}/4.5$, if the traffic is expressed in erlangs. The exact value, of course, depends on the degree of success in load equalization, but surprisingly enough the range is rather small considering the differences in the effort which various managements devote to proper line assignments. For the present study, therefore, $\sqrt{y}/4$ appears to be suitable for the standard deviation. This relation is quite plausible. If, for instance, it is found that the variance of the distribution of a set of subgroups with small amount of traffic is $y/16$, and if the average traffic of larger groups is formed by n such subgroups each, then the variance of the distribution of such groups will be $ny/16=Y/16$ and its standard deviation $\sqrt{y}/4$. The ratio of the stand-

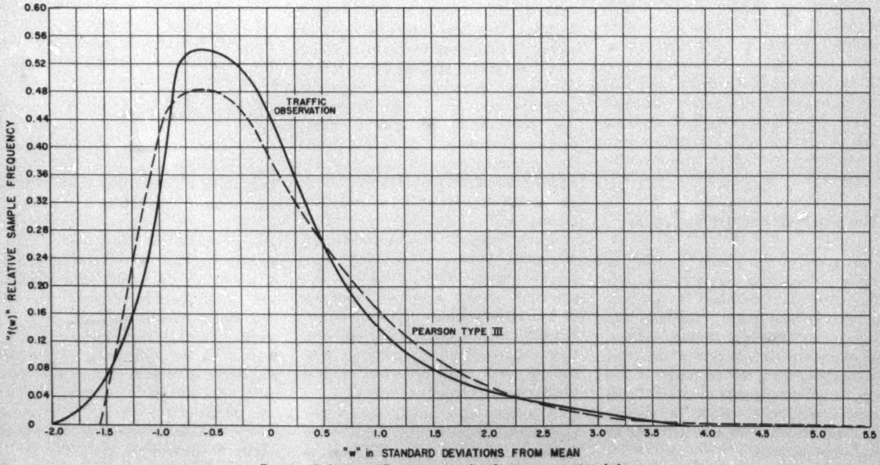

Fig. 8. Relation of Pearson-type distribution to empirical data

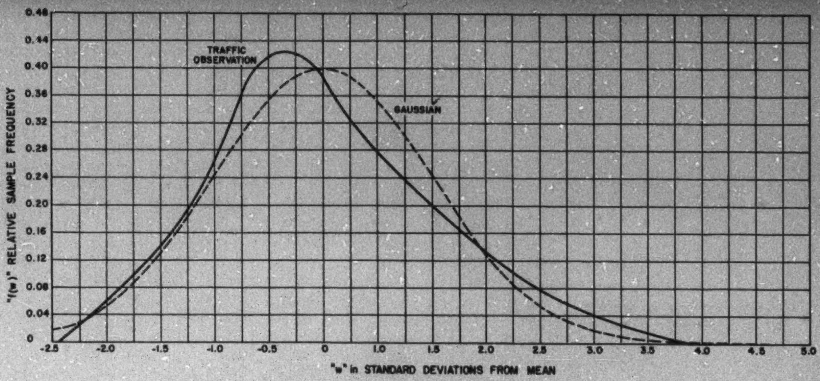

Fig. 9. Relation of Gaussian-type distribution to empirical data

ard deviation to the mean will, therefore, decrease in the ratio $1/\sqrt{y}$ with increasing average traffic. Now, very small subgroups with very small traffic have a Poisson distribution of their calling rate with a variance equal to the mean calling rate, and if this calling rate is multiplied by an average holding time of 1/20 hour, which is an appropriate value for this purpose, the standard deviation of such distribution will be $\sqrt{y}/4.5$, and the hypothesis as to combination of larger groups from such small ones follows.

Another common characteristic of all the distributions is their pronounced skewness (see Figs. 8 and 9). The distribution mode is decidedly to the left of the mean and the tails of the distribution become insignificant beyond two standard deviations to the left, but may extend over three or more standard deviations to the right. Actually one might have expected a Gaussian distribution of the subgroup traffic. If, for example, there are 95 groups of 96 lines, the traffic in each group will be the mean traffic of its lines, multiplied by the constant factor 96. According to the central limit law, no matter what the distribution of traffic over individual lines is, with increases in the number of groups, the distribution of the average traffic of the individual groups will tend to be normal. As the mean of the distribution was determined within an accuracy of ±3% at 0.95 confidence level, even a casual glance will show, and a test for goodness of fit will confirm this, that the distribution has no semblance of normality. A sample size of 95 should be sufficient to reveal normality, the traffic generated by subgroup sizes of 96 lines too small to remove the control of the population. Indeed, if the 95 subgroups are combined into 48 at random, and these into 24, etc., the range of the distribution gradually narrows, and the skewness becomes progressively smaller, until the samples and class marks are too few in number to be statistically meaningful.

Instead, when the 95 independent subgroups are organized into several ranges according to their busy-hour traffic, the number of subgroups belonging to each range form a frequency distribution. The set of subgroups can be looked upon as a sample of a hypothetical parent population, where the probabilities belonging to the various ranges are statistically reflected in the sample frequency distribution. The joint probability distribution of these range frequencies is the multinomial distribution, which with increasing number of subgroups tends to a joint normal distribution. This limiting distribution is closely related to the Pearson type III form which is also suggested by the shape of the empirical distribution.

The Pearson Type III Distribution

If the variable is standardized, this distribution is expressed in a form where skewness $g=2/M$ is the only parameter

$$f(w)=K(w+M)^{M^2-1}-Mwe^{-Mw} \tag{13}$$

Skewness g in the empirical distribution is defined as the ratio of the third moment about the mean to the cube of the standard deviation. Traffic variable w now is in units of the standard deviation with the mean at

$$w=0$$

$$M=2/g$$

$$K=M^{M^2}\exp(-M^2)/G(M^2)$$

and G is the gamma function. The distance on the abscissa between mean and mode is $-g/2$, function $f(w)$ is defined only in the range between $-M$ and infinity, and $f(w)$ is zero at $w=-M$ and asymptotic to the abscissa at infinity.

The Pearson-type distribution corresponding to the empirical data is shown dotted in Fig. 8, with the empirical skewness of 1.277. The match may not look particularly close, but it is quite good considering that at 95% confidence level the standard deviation is known only within 15%, and that there is also a limit to the accuracy of the skewness as well as in fitting the distribution to the frequency histogram. However, that the Pearson distribution is cut off at $w=-1.566$ instead of about $w=-2$, its lower modal frequency, its very long tail extending well beyond three standard deviations, and its general tendency would provide a very conservative value for the adjustment of c. In the sample frequency distribution the mean value of y was 2.572 erlangs and the standard deviation 0.382 erlang.

The cumulative probability distribution, that is, the area under the frequency-distribution curve from a point W to infinity, can be computed with the aid of a table of incomplete gamma functions as

$$\text{probability}(W<w)=\int_{W}^{\text{inf}} f(w)$$

$$=1-G_{M(W+M)}(M^2)/G(M^2) \tag{14}$$

Summing up the discussions of the last two sections, $f(w)$, as expressed by equation 13, approximates the distribution of the subgroup busy-hour traffics about their average y. Based on equation 14, the

Table I. Probability Distribution of Traffic

probability that a subgroup has a busy-hour traffic within some given range W_1 and W_2, or, in other words, the expected number of subgroups in this range relative to the total number of subgroups, can be obtained by the difference of the two corresponding incomplete gamma functions.

In Table I the deviation of subgroup traffic, in units of standard deviation, is given in the first column, the probabilities according to the traffic study and to the Pearson-type distribution as shown in Fig. 8, are given in the second and third columns respectively, and the corresponding probabilities by a normal distribution are given in the fourth column.

It may be noted that over most of the range it would be conservative to use the normal distribution than the Pearson distribution because of the higher proportion towards the above-average traffic values and lower proportion towards the lower-than-average traffic values, which would tend to bring about higher loss. Conversely, below −1 standard deviation the normal distribution shows an excess of 4%, while above +2.5 standard deviations the Pearson distribution has an excess of 3%, whereby an assumption of normal distribution would tend to reduce the loss. The Pearson distribution is more severe than the actual frequency distribution obtained from traffic measurements, in that the Pearson distribution gives greater weight to the subgroups with above-average traffic. This is also apparent from inspection of Fig. 8. In fact, the normal distribution is far more severe than the actual frequency distribution, except in the range below −1 standard deviation. The adjustment will be computed according to both the Pearson and the normal distributions, the Pearson to be used in more severe cases of expected unbalance, and the normal for applications where the load equalization is better than usual. Fig. 9 shows an empirical distribution with an average traffic of 4.964 erlangs per subgroup and 0.520-erlang standard deviation, and also a Gaussian distribution as a comparison.

The Principle of Adjustment

The loss function will be designated by $P(x, N)$, with x as the variable subgroup traffic and N the number of trunks as parameter. An attempt will be made to make $P(y+h, N+m)=P(y, N)$, with y as the average subgroup busy-hour traffic, h as an adjustment to the traffic, N the number of trunks required for y at the specified objective, and m the added trunks to obtain the same objective with the actual variation of the individual subgroup traffics. Because the adjustment is small, in the expansion of the foregoing expression all terms above the first order may be neglected. Therefore approximately the following is obtained:

$$\begin{aligned}P(y+h, N+m)-P(y, N)\\ =h\partial P(y, N)/\partial y+m\partial P(y, N)/\partial N \quad (15)\end{aligned}$$

The objective is to make the left side of equation 15 zero. This will happen if in the neighborhood of y and N the rate of increase of loss with increase of traffic is the same as the decrease of loss with the addition of trunks (and assuming fractional trunks could be added), with due consideration given to the scale factor h/m. That this is approximately true may be verified by computing the differentials, from a table of the Erlang function and its differences.

This can be simplified by analytic means. The denominator of the Erlang function $1+(x/1)+(x^2/2!)+\ldots\ldots(x^N/N!)$ can be approximated by e^{-x}, thus approximately $P(y, N)=e^{-y}y^N/N!$ which is, of course, the Poisson distribution. Then,

$$\begin{aligned}\partial P(y, N)/\partial y=P(y, N-1)-P(y, N)\\ =P(y, N)(N/y-1) \quad (16)\end{aligned}$$

The other partial derivative is

$$\begin{aligned}\partial P(y, N)/\partial N=P(y, N)(\log y-\\ (1/N!)\partial(N!)/\partial N)\end{aligned}$$

in which $\partial(N!)/\partial N$ can be obtained from the properties of the gamma functions, or by Stirling's approximation. Inserting this:

$$\begin{aligned}\partial P(y, N)/\partial N=P(y, N)(\log y-\\ 1/2N-\log N)\end{aligned}$$

the adjustment will be true if, approximately,

$$h(N/y-1)=m(1/2N+\log(N/y))$$

or, if after a series expansion of the logarithm, approximately,

$$h/m=1/2((N/y)-1)+1/(N/y))$$

The last equation can be verified numerically, for instance, by setting $m=1$ and reading out the corresponding differences h at several arguments of the Erlang tables. This usually is called the incremental trunk efficiency, which, as is well known, remains practically constant for a given grade of service when the value of change in traffic, c, is within a few per cent, and the value of traffic y is not too small.

Thus it seems justifiable to increase the average subgroup traffic y by an adjustment c, and to calculate the number of trunks with the new subgroup traffic $y^*=y+h=y(1+c/100)$ at the specified grade of service.

Adjustment c can be obtained from the requirement that the loss $P(y+h, N)$, when calculated with the original number of trunks N but with an increased average traffic $y+h$, remains the same as obtained from the actual distribution of subgroup traffics with the same number of trunks N. Therefore, first this loss $P(y+h, N)$ must be determined, then h can be found readily from the Erlang tables by extrapolating $y+h$ corresponding to N and $P(y+h, N)$.

The fundamental equation for $P(y+h, N)$ is

$$P(y+h, N)=\int_0^{\text{inf}} P(x, N)g(x)dx \qquad (18)$$

where $g(x)$, the distribution of the subgroup busy-hour traffic values, is the same as $f(w)$ from the preceding section, with x expressed in erlangs instead of the standardized variable w.

As a simplification, the Poisson form $e^{-x}x^N/N!$ is again substituted for $P(x, N)$ and thus

$$\begin{aligned}e^{-(y+h)}(y+h)^N/N!\\ =\int_0^{\text{inf}}(e^{-x}x^N/N!)g(x)dx=P(y+h, N)\end{aligned}$$

Inserting the Pearson type III distribution from the preceding section, after the change of variable w into x, and using the appropriate values for the skewness g, and $\sqrt{x}/4$ for the standard deviation,

$$P(y+h, N)=\int_q^{\text{inf}} Qx^A(x-q)^Be^{-Cx}dx \qquad (19)$$

Constants A, B, C, Q, and q can be derived from N which is given in the Erlang tables for the value y at the specified grade of service and from the constants of equation 13 by substitution. Equation 19 can again be solved with the aid of the incomplete gamma functions, after expansion of the binomial $(x-q)^B$. If B is not an integer, the variable may be changed again to $u=(x-q)$, since either

A or B or both will be an integer. Finally, h can be obtained from $P(y+h, N)$ through equation 17. The algebra and arithmetic are straightforward though lengthy for more than a few trunks N. Unfortunately the case of few trunks is of little importance.

Alternately, if the error function is used instead of the Pearson distribution for $g(x)$ a binomial expansion and a series of incomplete gamma functions will also result. The computation work in this case is less but the use of the error function is not appropriate for most applications. The approximate method to be described in the next section is simpler and its accuracy is adequate for this case.

Numerical Evaluation of the Adjustment

The starting point is again equation 18. By application of the theorem of the mean for integrals, this can be expressed as

$$P(y+h, N) = P(\bar{x}, N)\int_{0}^{\inf} g(x)dx$$

where $\bar{x}$ is the mean value of the variable. The right side can be expanded in a sum of integrals, each covering successive intervals, and each multiplied with the loss function $P(\bar{x}, N)$ at the mean value $\bar{x}$ of the variable within the interval. The intervals may range $w<-1$, -1 to -0.5, ... $+2.5$ to $+3$, $+3<w$, in units of standard deviation.

Step 1. Compute the integrals for each interval. This has been done already, in Table I, columns 3 and 4, for the Pearson type III and the normal distributions, respectively.

Step 2. Determine the mean value of the variable $\bar{w}$ for each interval, by means of the relation: $\bar{w} = \int wf(w)dw$, with both integrations carried out between the limits of the interval. The numerator was computed already under Case I for the normal distribution. For the Pearson type III distribution it will be of the form $\int w(w+q)^{B}e^{-Cw}dw$, which again can be computed by incomplete gamma functions, or, alternately, by mechanical integration. The first two steps are inherent properties of the functions, independent of traffic values and number of trunks. The computed set of values will be valid for all values of traffic and grades of service, as long as the validity of the distribution function and the numerical value of its parameter are accepted.

Step 3. Convert the standardized variable w to the traffic variable in erlangs by $\bar{x} = y + \bar{w}\sqrt{y/4}$.

Step 4. With the value of $\bar{x}$ obtain $P(\bar{x}, N)$ for each interval from a table of the Erlang function. This step needs some justification. While $\bar{x}$ is the mean value of the variable within an interval, the loss $P(\bar{x}, N)$ will be the mean value of the loss $P(x, N)$ for the interval only if its value changes linearly therein. In general, it will not be so, because then there would be no need for adjustment c. However, if the interval is narrow, say 0.5 standard deviation, the Erlang function is sufficiently linear for present purposes. As a matter of fact, at a traffic of 2.5 erlangs, for instance, 0.5 standard deviation is about 0.2 erlang, and the arguments of the tables are in steps of 0.1 erlang only. The most accurate tables are computed to six decimals, and they permit linear interpolation between steps to an accuracy of four decimals. If the grade of service is on the order of $P=0.01$, linear interpolation in steps of 0.1 erlang yields an accuracy to three significant figures. A check over several typical ranges showed that the second difference of P is nearly constant within 0.5 standard deviation of the argument, and is less than 4% of P. Therefore, the assumption that the mean value of the variable x coincides with the mean value of the loss $P(x, N)$ will be sufficiently accurate for the present purposes. At very low traffic values, about 1 erlang and below, the linear interpolation is somewhat less satisfactory, but at such values the use of Erlang's theory for traffic engineering is also objectionable for other reasons and is to be avoided if one tries to be realistic.

Step 5. Multiply each value of $P(\bar{x}, N)$ obtained in step 4 by corresponding probability $\int f(w)dw$, found in Table I, and add all these products.

Step 6. The sum obtained in step 5 is the loss $P(x+h, N)$. Enter this value into the Erlang tables at N specified for y with the objective grade of service, and find $y+h$.

Step 7. The value of added fictitious traffic will now be $h=(y+h^{*})-y$, and the adjustment $c=100h/y\%$.

Tables II and III list some typical computation results.

The values in Table II were prepared under the assumption of Pearson type III distribution for the busy-hour traffic of subgroups, similar to the one shown in Fig. 8. The adjustments are substantial, and practically the whole amount was contributed by the long tail beyond +3 standard deviations. Table III was based on normal distribution with the same standard deviation as Table II. The adjustments are more moderate here.

Adjustments to be added to the average subgroup busy-hour traffic y for the

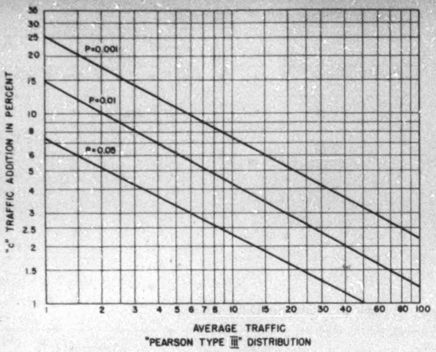

Fig. 10. Traffic adjustment for various grades of service with Pearson-type distribution

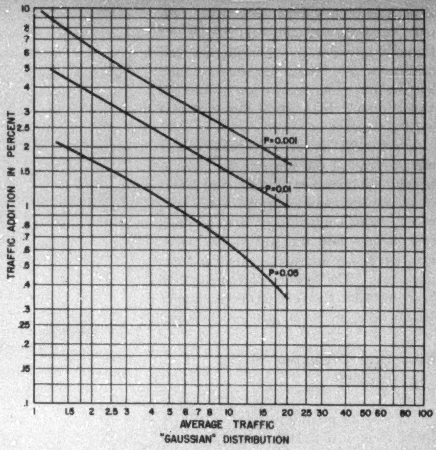

Fig. 11 (right). Traffic adjustment for various grades of service with Gaussian-type distribution

calculation of trunk quantities for various grades of service are shown in Fig. 10 and 11 for the Pearson and normal distributions, respectively. The graphs show in most parts nearly perfect linear relationship when drawn on a log-log scale. The actual tabular values reveal an almost imperceptible curvature.

Several distributions of the traffic studies were compared with the preceding theory at various average traffic values and at various grade-of-service objectives. The adjustments needed to bring the grade of service up to the objective were computed for the actual distribution, and it was found that such adjustments should be between those shown in Figs. 10 and 11, about two thirds of the way towards the Pearson-type distribution.

In conclusion, grade-of-service specification 2 prescribes that the loss of the individual subgroups in their respective busy hours, on the average, should not exceed a given amount. Then the average subgroup traffic should be increased by a certain amount *c*, and the number of trunks for the subgroups should be based on the increased average traffic. The adjustment depends on the average traffic as well as on the required grade of service, and its value can be found in Figs. 10 and 11. Fig. 10 is to be used when no attempts were made to equalize the traffic between the subgroups and Fig. 11 is to be used when special provisions assure good equalization. For the average case adjustments intermediate between Figs. 10 and 11 are suggested. When the subgroups are perfectly equalized, or if the subgroup traffics are individually known, there is, of course, no need for adjustment. The adjustment for subgroup variation is independent of and in addition to the adjustment for busy-hour phase shift. The latter was discussed under Case I, and is applied to obtain the average subgroup busy-hour traffic from the subdivided office busy-hour traffic.

Average Daily Grade of Service of Subgroups

Grade-of-service objective 3 required that the average total daily loss of all subgroups of a rank should not be more than a given amount. The exact amount of the loss is irrelevant, and can always be expressed in equivalent subgroup losses. From the traffic engineering point of view, this specification is comparable with the previous one for the computation of trunk quantities. The number of trunks is based on group busy-hour traffic, and adjustments *a* and *c* are applied as before. The only item still needed is the conversion factor between group busy-hour losses and the total-day's loss.

In Fig. 5 the decrease of traffic *b* adjacent to the busy hour is given. Assume now, as was done under Case I, that there will be two side hours with traffic y' and two side hours further removed with traffic $y''=y'(1+y'/y)/2$. There may be an additional hour with traffic comparable to y'. The remaining hours during the day will contribute negligible amounts to the total loss. This total loss is obtained by computation of the individual loss for 1 hour with y, 3 hours each with y', and 2 hours each with y'', and adding all these together. Table IV shows typical multipliers for full-availability trunking.

Two facts are apparent. The first is that for any grade of service the multiplier remains quite constant within a large range of traffic values, though it becomes smaller as traffic increases. The second fact to note is that the multiplier becomes smaller as the busy-hour grade of service improves.

Accordingly, for the most commonly used grade of service $P=0.01$ and the usual few erlangs of traffic volume found in subgroups, the total-day's loss would be about twice the busy-hour loss.

Table IV relates the traffic to the subgroup busy-hour grade of service. The objective set under specification 3 limits the average daily loss to a certain figure. It has been learned that the individual-subgroup traffics vary considerably about their average. When $N+m$ trunks were provided, *m* was determined by the desire to keep the average busy-hour loss within the objective, and for the purpose of trunk calculation the average group busy-

Table IV. Typical Multipliers for Full-Availability Trunking

Traffic, Erlangs	Total-Day Multiplier for Busy-Hour Loss		
	P=0.05	P=0.01	P=0.001
1.4	2.7	2.0	1.5
2.5	2.8	2.1	1.5
5.2	2.8	2.1	1.5
20.0	2.4	1.8	1.3
100.0	1.65	1.17	1.04

hour traffic y was increased by the amount h. Even though the average group busy-hour loss will now equal the objective, some groups will show higher-than-average, and a larger number of groups will show lower-than-average loss. According to Table IV the groups with higher-than-average loss require a larger multiplier to obtain the total-day loss while the other groups require a smaller multiplier, though otherwise each multiplier will remain constant over the range of traffic variations of these subgroups.

The over-all multiplier is designated J, and in general $J(P)$ will be a function of the loss P, and will depend on the traffic only through P. The daily average loss will be $JP(y+h,\ N+m)$, where $P(y+h,\ N+m)$ is the objective busy-hour loss $P(y,\ N)$. The daily average loss will also equal the sum of terms $J(P)P(\bar{x},\ N+m)\int g(x)dx$, and as $P(y+h,\ N+m)$ is the mean value of $P(\bar{x},\ N+m)$, J will be the mean value of $J(P)$. If the change of $J(P)$ with $P(x,\ N+m)$ is linear relative to the variable x within the range of subgroup traffic variations, then the over-all multiplier J which should be applied to the average busy-hour loss $P(y+h,\ N+m)$, will be the value of $J(P)$ corresponding to the mean value of $P(xN,\ +m)$, which, however, is just $P(y+h,\ N+m)$. This value of $J(P)$ $(y+h,\ N+m)$ can be found in Table IV. The assumptions of linear change of $J(P)$ and the propriety of the over-all multiplier were numerically verified at several typical values.

Therefore, the average grade of service provided to this rank, that is, the total-day's loss of n adjusted subgroups, will equal the average subgroup busy-hour loss $P(y+h,\ N+M)$ with average subgroup busy-hour traffic y and $N+m$ trunks in each subgroup, multiplied with the proper factor from Table IV. Whether the average busy-hour loss is the starting point, or whether the other parameters are established from the specified average total-day's loss, is irrelevant to the discussions in this section.

It is interesting to note that if adjustment c is not applied to the average traffic y, but only the number of trunks N corresponding to the average traffic are provided, then the daily-loss multipliers for the different busy-hour grade-of-service objectives will be much closer to each other than those listed in Table IV. The reason for this is that while the multipliers increase with increasing busy-hour loss, the amount $[P(y+h,\ N)-P(y,\ N)]/P(y,\ N)$ decreases with increasing busy-hour loss, and the two tendencies will compensate each other to some degree. For the lower traffic values the multiplier will vary between 2.9 and 3.9 (3.9 for $P=0.001$), and for about $y=20$ erlangs between 2.1 and 2.6 (2.1 for $P=0.001$).

For graded trunk groups the multiplier has somewhat different values. At $P=0.01$ it is about 2.3 to 2.4 between 10 and 25 erlangs.

Office Busy-Hour Grade of Service

Grade-of-service specification 4 requires that the loss during the office busy hour should not exceed the objective. Considering again a certain rank, for example, all connectors in the office, the combined office busy-hour loss of the connectors is the sum of the losses of the individual connector groups during the office busy hour.

The average traffic of a connector group is Y/n, where Y is the total office busy-hour traffic of the connector rank, and n the number of connector groups, as before. This traffic will also show variation from group to group, as did the group busy-hour traffic y before, but, in addition, this variation will be superimposed on a variable mean value between the limits y and y' due to the phase shift of the group busy hours. The mean traffic of the latter variable will be, of course, Y/n, and the factor A from Case I is a measure whether Y/n lies closer to y or to y'. Examination of Figs. 5 and 6 reveals that at about 2 erlangs Y/n is about halfway between y and y'; below this it is closer to y', and above closer to y. Above about 20 erlangs it is practically wholly composed of y.

In Case I, the conclusion was reached under the assumptions made there, that the prorated average subgroup traffic Y/n during the office busy hour may be considered as composed of two components: 1. Ay, from those subgroups whose subgroup busy hour hypothetically coincides exactly with the office busy hour; and 2. $(1-A)y'$, from the subgroups which with their side hour completely cover the office busy hour. Adjustment c of the first component is to be computed by insertion of y into the equation for $P(y+h,\ N+m)$, and adjustment of the second component is to be computed by insertion of y' into the equation $P(y'+h',\ N+m)$.

If the change of loss function $P(x,\ N)$ were linear within the range between y and y' with change of x, that is, $P(x_1,\ N)/P(x_2,\ N)=x_1/x_2$, the loss at Y/n would be $P(Y/n)+h^*,\ N+m)$, where h^* is the traffic increase for Y/n, and adjustment $c(Y/n)$ could be read from Figs. 10 and 11 at abscissa Y/n. As can be seen from Fig. 5, the distance between y and y' is about 35% at 1 erlang, 26% at 2 erlangs, and 18% at 5 erlangs. At low traffic values, say below 2 erlangs, and particularly below 0.01 grade of service, the second differences of the loss functions are not negligibly small within the range y to y', so a better approximation is required.

In the following, $Y/n=y^*$ will be designated y^*. The traffic adjustment per subgroup is again h, corresponding to average subgroup busy-hour traffic y, and the adjustment corresponding to the office busy-hour average traffic y^* will be h^*, which can be obtained from Figs. 10 and 11. It can be suspected, however, that, due to the subgroup busy-hour phase shift, this adjustment must be increased, say to h^*+q, and the adjusted actual number of trunks N (which were formerly designated $N+m$) may be then found from the Erlang tables at the argument y^*+h^*+q.

The average office busy-hour loss will be composed of the sum of elementary losses, similar to the integrand of equation 18, say $P(x,\ N)g(x)dx$, with the conditional probability that the mean value of the variable subgroup traffic x of that particular subgroup during the office busy hour is z. The unconditional probability for the latter is $f(z)dz$. As the two distributions, $g(x)$ for the variation of subgroup traffics because of inadequate equalization and $f(z)$ for the phase shift of subgroup busy hours, are independent of each other, then

$$P(y^*+h^*+q,\ N) = \int_x \int_z P(x,\ N)g(x)f(z)dzdx \quad (20)$$

The limits of integration do not need to be defined explicitly for the moment; in general they will cover the whole range of possible variations of x, and z will be limited between y and y'. The order of integration is immaterial in the present case. $\int P(x,\ N)gx\ dx=P(z+h,\ N)$ from equation 18. Now $P(y^*+h^*+q,\ N)$ is expanded into a Taylor series:

$$P(y^*+h^*+q,\ N)=P(y^*+h^*,\ N)+ qdP(y^*+h^*,\ N)/d(y^*+h^*)+\ldots$$

The second derivative of P is fairly small, even at low traffic values and $P=0.001$, and q is very small, perhaps a few per cent of P. Therefore, second- and higher-order terms may be omitted.

From equation 16

$$dP(y^*+h^*,\ N)/d(y^*+h^*) = P(y^*+h^*,\ N)(N/(y^*+h^*)-1)$$

and

$$P(y^*+h^*+q,\ N)=P(y^*+h^*,\ N)\times [1+q(N/(y^*+h^*)-1)]$$

Furthermore, $z+h=y^*+h^*+(z-y^*)+j$ are set where $z-y^*$ is the variation of subgroup traffic about Y/n during the office busy hour, and $j=h-h^*$ is the variation of the adjustment h about h^*. Expanding again, and with the same approximation as before

$$P(z+h,\ N)=P(y^*+h^*,\ N)+(z-y^*+j)\ dP(y^*+h^*,\ N)/d(y^*+h^*)+\ldots$$

$$=P(y^*+h^*,\ N)[(1+(z-y^*+j)\times(N/(y^*+h^*)-1)]$$

Combining the preceding equations and after some simplifications

$$1+q(N/(y^*+h^*)-1)=\int 1+(z-y^*+j)\times(N/(y^*+h^*)-1)f(z)dz$$

The integral $\int f(z)dz=1$ if extended over the whole range of possible values of z, by definition. Thus

$$q=\int(z-y^*+j)f(z)dz$$

The integral $\int(z-y^*)f(z)dz=0$ since y^* is the mean value of z within the range also be definition. Finally

$$q=\int jf(z)dz \qquad (21)$$

Observing that adjustment $c=100\ h/y$, and that Fig. 10 suggests the form $c=J/y^K$, the following empirical approximate relations are obtained:

$$\left.\begin{array}{l} h=0.25\ \sqrt{y} \text{ for } P=0.001 \\ h=0.15\ \sqrt{y} \text{ for } P=0.01 \\ h=0.075\sqrt{y} \text{ for } P=0.05 \end{array}\right\} \qquad (22)$$

It is interesting to note that for $P=0.001$ the adjustment is the same as the empirical standard deviation for $g(x)$ and that the adjustment is about halved in each of the foregoing steps between grades of service. Now, $j=h-h^*=J(\sqrt{z}-\sqrt{y^*})=J\sqrt{y^*}(\sqrt{(z/y^*)}-1)$, where J is one of the constants in equation 22.

Now consider $f(z)$ and the limits of integration. $f(z)$ is the frequency distribution of subgroups with traffic z during the office busy hour. In Case I it was shown that the office busy-hour traffic z varies between y and y' according to $y-t_0(y-y')$ (only absolute values of t_0 taken) between $-1<t_0<+1$, and stays y' beyond. t_0 was the center point of the group busy hour, the center point of the office busy hour being 0.

The distribution of t_0 was assumed to be normal with $1/T$ standard deviation. If the foregoing limits are disregarded for the moment, it may be said that the distribution of z will be normal, with $(y-y')/T$ as standard deviation.

By a change of variable $u=T(y-z)/(y-y')$ the distribution $p(u)$ will be normal with unit standard deviation. $u=0$ will be at $z=y$. Only values $u>0$ will be considered, and as t_0 may take positive as well as negative values yielding the same z, the frequency for each interval (u to $u+du$) will be $2p(u)du$. The lower limit of integration is at $u=0$. The normal distribution is incomplete and stops at T standard deviations, where the variable $z=y'$.

Beyond $u=T$, the variable $z=y'$ over the whole tail of the normal distribution.

Equation 21 will now read:

$$2T/(y-y')\int jp(u)du$$

and

$$j=J\sqrt{y}[(1-u(1-y'/y)/T)^{1/2}-\sqrt{(y^*/y)}]$$

Under Case I, $(1-y'/y)$ was $b/100$, the decrease of traffic from the busy hour to the adjacent hour (relative to y), or b if expressed as a fraction instead of as a percentage. The limit of integration is T, and what is beyond is small, so the term ua_1/T, in general, will be less than 1, on the order of 0.35 or less according to Fig. 5. Thus

$$(1-ub/T)^{1/2}=1-ub/2T$$

approximately. The error of this approximation is on the order of 0.01 in the worst case of practical significance. It decreases rapidly with increasing traffic and, furthermore, it is on the conservative side. Therefore,

$$j=J(\sqrt{y}-\sqrt{y^*})-Jub\sqrt{y}/2T$$

approximately. Again, $y^*/y=1-a_1$ from Case I, if a_1 (Fig. 7) is expressed as a fraction instead of as a percentage, a_1 is the adjustment for the busy-hour phase shift, which is subtracted from y to obtain $Y/n=y^*$. Finally

$$j=J\sqrt{y}(1-\sqrt{(1-a_1)}-ub/2T) \qquad (23)$$

also, from equation 21,

$$q=2T/(y-y')\left(\int_0^T jp(u)du+ j(u=T)\int_T^{\text{inf}} p(u)du\right) \qquad (24)$$

After some rearrangements, keeping in mind that

$$2\int_0^{\text{inf}} p(u)du=1$$

$$q=[2TJ\sqrt{y}/(y-y')][1-\sqrt{(1-a_1)}]-(2Jb\sqrt{y}/(y-y')\left(\int_0^T up(u)du+ T\int_T^{\text{inf}} p(u)du\right)$$

$$=[2J\sqrt{y}/(y-y')]\left\{T[1-\sqrt{(1-a_1)}]- b[p(0)-p(T)]-bT\int_T^{\text{inf}} p(u)du\right\} \qquad (25)$$

As before, $p(u)$ is the tabulated error function and $\int p(u)du$ the tabulated error integral.

At grade of service 0.001, the adjustment values from equation 25 are 2.16%, 1.01%, and 0.73% at Y/n 1, 2, and 5 erlangs, respectively. For a grade of service 0.01 or 0.05, the adjustments are about one half or one fourth of these, corresponding to the values of J in equation 22. This fictitious incease is over and above the increase c due to subgroup traffic variation, and supposed to be used in determining the number of trunks per subgroup from the prorated office busy-hour traffic Y/n, to protect the specified average grade of service during the office busy hour. Now, from Fig. 10 the adjustments c corresponding to the foregoing traffics at 0.001, were 25%, 17.5%, and 11%; and it will be recalled that there was considerable latitude in the choice of intermediate values between Figs. 10 and 11, depending on the degree of traffic equalization in a particular application. The magnitude of q is probably less than the error in judgment in the choice of intermediate values between Figs. 10 and 11, therefore (in case of grade-of-service specification 4) if in the choice of c Fig. 10 is used, adjustment q may be disregarded.

A few words may be in order on the possible errors in these discussions. In addition to the assumptions listed under Case I, in several series expansions second- and higher-order terms have been neglected, and also the Poisson function substituted for the Erlang function. Other possible sources of error can be found in linear interpolation of tabulated functions. In addition to these analytic errors, there were others made when the distribution functions for the subgroup traffic variation, side-hour traffic decline, and busy-hour phase shift, as well as their parameters (mean, standard deviation, and skewness) were determined from a limited amount of empirical information. Compared with these statistical uncertainties, as expressed by the latitude given between Figs. 10 and 11, the analytic errors are trivial. But even including the statistical errors the various adjustments appear to be close enough, if the limited accuracy of traffic information available for practical applications, the vagueness in what can be considered good grade of service, and the degree to which the various theoretic loss formulas come close to the facts of life are considered.

Superficially, it may seem that the discussions related to grade-of-service objectives 3 and 4 are contradictory. Consider the example of an office with 10,000 stations originating 250 erlangs busy-hour traffic. The stations are divided into 100 groups with 100 stations each, with a prorated average traffic Y/n of 2.5 erlangs per groups. If specification 2 is followed, say at the grade of service 0.01, adjustment $a=12.5\%$ from Fig. 6 must first be applied, so that the group busy-hour traffic will be 2.82 erlangs. Each group will lose 0.0282 erlang in its busy hour, or 2.82 erlangs for all 100 groups. The total-day's loss of all 100 groups will be, according to Table IV and specification 3, $2.1\times 2.82=5.92$ erlangs, which is $2.35\times 0.01\times 250$ erlangs. To obtain the number of trunks per group, add to 2.82 erlangs a second adjustment c, which is 2.4% from Fig. 10, so $y+h=2.9$ erlangs, which require 7.8 trunks.

If specification 4 is followed, the average traffic per subgroup will be 2.5 erlangs; $c=2.6\%$ is added and 7.2 trunks per group specified for 2.57 erlangs. It may be reasoned that since the trunks were computed for the office busy hour for a grade of service 0.01, that is, with a loss of $0.01\times 2.50=0.025$ erlang, the total-day's loss for the rank according to Table IV should be $100\times 2.1\times 0.025=5.25$ erlangs, which is 13% less than obtained under specifications 3 with about 8% more trunks.

Actually, no matter which way the number of trunks is figured, each group will still carry in its busy hour on the average the same 2.82 erlangs traffic, and the group busy-hour grade of service now, with only 7.2 trunks, will be 0.0166 instead of 0.01 with 7.8 trunks. The total-day's loss is perhaps $2.2\times 0.0166\times$ 2.82 erlangs for each group, and 100 times as much for 100 groups, or 10.3 erlangs altogether, or $4.13\times 0.01\times 250$ erlangs. This is 75% more than with 7.8 trunks per group and nearly twice as much as was suggested earlier in this paragraph.

The fallacy of the reasoning is that it did not take into consideration the fact that objective 4 is concerned only with the grade of service during the office busy hour, and is satisfied that, in general, during the rest of the day, the service is better. Objectives 3 and 4 represent completely different concepts, and there is no simple connection between them other than the relationship revealed by analysis in this paper.

The Office Grade of Service

The preceding discussions were all concerned with measures for sustaining the grade-of-service objective in a single switching rank. However, a telephone office contains several switching ranks, and some consideration must be given to the over-all grade of service provided by the office. For example, consider a central office consisting of a primary rank, four ranks of selectors, and one rank of connectors; and again, the total office busy-hour traffic is 250 erlangs. The subgrouping in the primary rank is extensive, in groups of 100 or 200 lines, and, likewise, the connectors are arranged for 100 terminals in a group. The selector rank preceding the connectors consists of groups carrying traffic to 1,000 terminals. The two sets of trunks between the remaining three selector ranks carry the large volume of intraoffice traffic as well as traffic to other switching offices. In addition, there will be trunks to the third selector rank which receive traffic from other switching offices.

To begin with the interoffice trunking, there is no generalization possible about the outgoing and incoming traffic volumes relative to the total, nor as to the location of the group busy hours relative to the office busy hour, because these will depend on peculiarities of local situations. Therefore, the previous rules for subdivision, in general, will not be applicable, since they refer to a more or less random subdivision. Instead, the traffic in each trunk group should be appraised from whatever individually pertinent information is available. On the other hand, Figs. 6 and 7 are still useful to express the relationship between the group and office busy-hour traffics on such trunk groups, in the absence of more definite information.

Assume now that the total traffic leaving the office and the total traffic received from outside are equal and that their over-all busy hours coincide with the office busy hour. These assumptions simplify the problem and are very nearly true in many situations. Where the assumptions do not fit, the general principles developed in these discussions should enable modifications to be applied. The intraoffice traffic is carried in one large volume and requires no adjustments for subdivision.

Due to the fact that switching does not commence until dial tone is received, the number of trunks per group in a primary rank is computed differently from the methods used in the previous discussions. In spite of these differences, whether the grade of service is based on calls being lost or delayed, the consequences of subdivision are similar, and so to simplify matters further it is assumed that the trunking in the primary rank is based on grade-of-service specification 2 or 3, with the adjustments for subdivision carried out accordingly. The adjustments for the connector rank, that is, for the computation of the trunks from the selectors preceding the connectors, were discussed fully in previous sections. The trunks preceding the last rank of selectors are divided into ten groups carrying on the average 25 erlangs traffic in the office busy hour. The two adjustments, one for busy-hour phase shift and the other for group variation, are again based on the previous principles, with 25 erlangs average group traffic.

The end result for the whole office, however, will be something unexpected. Take a call originated during the office busy hour in one of the primary subgroups and assume objective 2 with a loss of 0.01 during the subgroup busy hour. If the subgroup busy hour coincides with the office busy hour, 1% of the attempts will be lost, and similarly in those ranks where the trunking was based on the office busy hour. In other ranks, for instance, interoffice trunks based on group busy hours, as well as in the connector rank and the selectors preceding it, and computed to objective 2, during the office busy hour less than 1% of the attempts are lost on the average, so the grade of service received will be better than the sum of the grade-of-service objectives over all ranks. If the busy hour of the primary group was away from the office busy hour, the grade of service will be still better, because, on the average such calls will terminate in groups having their side hours at that time.

Now, objective 2 attempted to provide an average grade of service to the aggregate of subgroups, and to equalize the effect of the busy-hour phase shift. But the end result is that while the groups with their busy hour during the office busy hour will suffer a slightly higher loss than the others, all the groups will have less loss than 0.01 times the number of switching ranks. This is not necessarily undesirable, nor in conflict with specification 2, but it could hardly be anticipated from the stated objective.

If specification 4 is followed by application of adjustment h^*, or more precisely h^*+q, to Y/n, only enough trunks are provided to limit the loss in each rank and group during the office busy hour to, say, 0.01. A call originated during the office busy hour will then have 0.01 loss through every rank which has not been subdivided, in accordance with assumptions made that the same total volume of traffic is carried during the office busy hour through every rank. In those ranks which are subdivided, groups which have their busy hour during the office busy

Table V. Comparison of Objectives 3 and 4 Losses, in Erlangs

Trunks	Objective 3 Loss		Objective 4 Loss	
	Group Busy Hour	All Day	Group Busy Hour	All Day
Primary	2.82	5.92	2.50	10.3
First to second	2.50	6.00	2.50	6.0
Second to third	2.50	6.00	2.50	6.0
Third to fourth	2.55	5.35	2.50	6.8
Fourth to connectors	2.82	5.92	2.50	10.3
Total		29.19 (11.7% of 250-erlang office busy-hour traffic)		39.4 (15.8% of 250-erlang office busy-hour traffic)

hour will suffer a higher loss, and the other groups a lesser loss, but even in these ranks the loss will be equal on the average to the objective. Therefore, it appears that specification 4 can be more consistently administered through all ranks in the office, but also is more inconsistent in the grade of service between subgroups originating the traffic. As was mentioned before, the two objectives represent entirely different concepts for the grade of service: objective 2 protects an average grade of service, while objective 4 insures a better than minimum quality throughout the day.

These views can be extended to the whole day. It has already been learned that, for trunk engineering, objective 3 is equivalent to 2. But surprisingly, although it was just shown that all traffic originated in the subgroups during their group busy hour will have an over-all loss less than the anticipated objective, the total loss over all ranks and throughout the day will be almost exactly equal to the objective, or perhaps a trifle more. This will be apparent from Table V, and the reason for it is that the loss over all the ranks is spread over several side hours of the originating subgroups.

No specification equivalent to 3 can be found for 4 since 4 is inherently unconcerned with what happens outside the office busy hour. In view of Fig. 6 and Table IV, the relationship between objective 4 and total-day's loss must be highly dependent on the traffic and grade of service, which would be hardly worthwhile to develop. In the present example, the 10,000-station office with 250 erlangs busy-hour traffic, this comparison of objectives 3 and 4 can be made.

In Table V it was assumed that the primary groups consist of 100 lines each, that the same traffic is carried through each rank, and that the trunking between first and second, and second and third selectors were the same for both objectives, with an all-day multiplier of about 2.4 applicable to graded trunk groups. The total-day's loss of the whole office under specification 4 is of course higher by about 35%. With specification 4 the saving in equipment in the primary and connector ranks is about 8%, and in the rank preceding the connectors about 1.5%. The percentages lost as shown in the table refer to the office busy-hour traffic. If this is related to the total-day's traffic, assuming that the busy-hour contains about one tenth of the 2,500-erlang total daily traffic, the day's loss would be about 1.2% and 1.6% of the daily traffic, with specifications 3 and 4, respectively. From a practical point of view there is little noticeable difference between the two: objective 4 is satisfied with less equipment and is easier to administer because adjustment *a* need not be applied, but objective 3 is somewhat more equitable.

In addition to those discussed before, two more grade-of-service specifications may be worth considering.

5. For a central office, the grade of service given the combined traffic during a specified period, say over 24 hours of the average business day, should be equal in each rank, and should not be worse than the specified amount. This specification would be even more complex to administer than 3, because the methods of objective 3 or 4 would have to be applied to each rank with a busy-hour grade of service which anticipates the total-day multipliers. There would be nothing gained except some superficial symmetry. A more efficient objective is given in specification 6.

6. For a central office, the over-all grade of service given to the combined traffic of all ranks during a specified period say over 24 hours of the average business day, should not be worse than the specified amount, with the additional provision that the total cost of the equipment should be minimum.

Objective 6 is obviously the most efficient of all those discussed, but its administration is formidable. Not only must each rank be computed with a grade of service appropriate to the relative cost of the type of equipment employed in the rank, but to minimize the total cost the grade of service must also be modified according to the trunking method and the traffic in the rank. In practice this objective is being considered to a limited extent by assigning different grades of service to different ranks, which in a broad manner takes into account the relative costs of the types of switches.

It was already said that the guiding principles for the grade-of-service objectives are obscure, and that their theoretic measures are just broad approximations, based on a number of simplified assumptions, such as statistical equilibrium, Poisson distribution of attempts, disposition of calls during congestion, etc., which in many actual applications are not even approximately correct. Then what is the purpose of such grade-of-service objectives? There are three important justifications in addition to the fact that in surprisingly many cases the theoretic predications are borne out by traffic measurements, in spite of the unreality of the assumptions. First, experience has shown that if certain grade-of-service rules are followed, the day-by-day service results are very satisfactory to telephone users. Second, it provides an exact theoretic yardstick to compare the performance of widely different systems or arrangements. Third, and perhaps most important, a good grade of service protects the service from collapse during unexpected overloads by providing spare capacity for such eventualities. To see this, consider a traffic of 10 erlangs. At the grade of service 0.1 about 15 trunks are provided. If temporarily the traffic were to rise 50%, the trunks would be 100% loaded and unable to carry any additional traffic. On the other hand, on the basis of 0.01 19 trunks would have been provided, and they could carry almost 100% overload before the same catastrophic condition could occur.

Conclusions

In the preceding discussion various adjustments were developed, which are to be applied to average traffic values when large traffic volumes are subdivided and the number of trunks is determined for each subdivision with certain grade-of-service objectives to be satisfied. In general, the need for these adjustments arises because the busy hours of the subdivisions are shifted in phase relative to each other, and because in most cases it is impractical completely to equalize the traffic volumes between the subdivisions. There is a separate additive adjustment for each of the two causes; the first may be omitted if only the over-all busy-hour grade of service is of interest, and the second may be omitted if the traffic between the subdivisions is well equalized. The first adjustment may also be used to determine the contribution of a trunk group to the over-all busy hour if its group busy-hour traffic is known or vice versa.

The relations between the busy-hour grade of service and the total-day's grade of service were also developed. The grade of service to be provided by switching equipment can be prescribed from different points of view; in general these either attempt to protect the average grade of service given to the different subdivisions, or insure that the over-all service should not be degraded below a certain level during any one hour of the day. The most efficient objective minimizes the total cost of the equipment within the permissible grade of service. Its administration is very complex if an attempt is made to carry it to perfection.

The latitudes in the application of these adjustments are necessarily broad, consistent with the limitations inherent in all traffic engineering problems. These limitations include: diverse conditions in individual applications which prevent generalization, lack of pertinent data for such applications, practical limitations in control of fluctuations, vagueness in basic principles for grade of service, and deviations of actual conditions from the various simplified assumptions which are fundamental to the congestion theories.

Pagemaster Receiver and Modulation Equipment

J. W. YOUNG
NONMEMBER AIEE

AT PRESENT, there are many varied types of paging systems on the market which are applicable to the many types of services or industries requiring paging systems. Each of these, whether they be audio, inductive loop, r-f (radio-frequency), light, bell, or any other type of system, has certain advantages and limitations. The results of a comprehensive investigation of the paging field showed that there was a definite need and a market for a selective r-f paging system. In many instances such a system could adequately replace, with improved operation, the existing type of system. In other instances it could advantageously supplement an existing paging system with a resultant improvement in the over-all paging operation.

The results of the aforementioned study led to the development of a practical type of selective r-f paging system known as the Pagemaster* system. The Pagemaster system is a relatively new type of communication system whereby one of several thousand personal pocket-carried receivers may be selectively signalled. In essence, the system is a one-way signalling system in that no communication is initiated by the pocket-carried receiver. The receiver is essentially a signal-actuated device whereby contact is established but not maintained. The receiver will indicate that contact has been established by emitting an audible tone.

The emphasis to date has been placed on an industrial type of system which can accommodate 455 receivers. This industrial system has found wide acceptance in various industries and hospitals where 455 receivers would be more than adequate. However, the same principles used in the industrial system can be extended into a system capable of servicing 3,235 individual subscribers, and would therefore be adaptable to city-wide paging systems.

This paper will describe the coding and modulation system employed in this r-f paging system; the base station equipment required to code the information; and the receiver and its decoder.

System Operation

Before the modulation system and the components of the system, it might be advantageous to describe briefly its over-all operation. The city-wide paging system's operation is given in a companion paper.[1] An acquaintance with the complete operation will facilitate an understanding of the functioning of each of the components used to achieve the end result.

The complete system or installation is comprised of an encoder, a transmitter, an antenna, and any number of receivers. Since the system is selective, each of the receivers will have a number which will correspond to a predetermined code. In the system a total of nine different digits are used and, as will be explained later, each digit will correspond to a different audio frequency.

When it is desired to contact a person assigned a receiver, the calling party will contact the operator who has control of the base station equipment. The operator in turn will set the desired code into the encoder and place the equipment in operation. The output from the encoder which will be the coded modulating signal will amplitude-modulate the transmitter, and the desired code will be radiated from the antenna. All of the receivers in the system will receive this coded signal, but only the receiver with the proper code will respond, by emitting an audible tone. The called party will merely press a button on the receiver which will squelch the tone and reset the receiver automatically for the next call. Upon being paged, the called party will take some predetermined action, which is usually to call his office or some other designated telephone.

Coding and Modulation System

The nine different audio tones employed in the coding system range in frequency from 160 cps (cycles per second), which corresponds to digit 1 to 301.18 cps, which corresponds to digit nine. The frequencies corresponding to each of the digits are shown in Table I. The choice of the audio frequencies was dictated by the decoding mechanism in the receiver which utilizes tuned vibrating reeds, to be discussed in connection with the receiver.

The coded signal will consist of sequential bursts of the appropriate audio frequencies. Fig. 1 shows the modulating signals employed in the 3-digit and 4-digit systems. In the 3-digit system, which is synonymous with a 3-reed system, the transmitted signal consists of a carrier

Table I. Frequencies Relating to Digits

Tone	Frequency, CPS	Division Factor	Feedback Applied, Stage No. 2	3	4	5
1	160.00	128	no feedback			
2	170.67	120		X		
3	182.86	112			X	
4	196.92	104		X	X	
5	213.33	96				X
6	232.73	88		X		X
7	256.00	80			X	X
8	284.44	72		X	X	X
9	301.18	68	X	X	X	X

amplitude modulated with three sequential bursts of audio frequency. Each of the bursts are 0.5 second in duration with a gap of approximately 0.15 second between the bursts. The coded signal is therefore 1.8 seconds in duration with a guard time of 3.2 seconds between code groups. As an example, assume that receiver 179 is to be paged. The coded signal would consist of a 0.5-second burst of tone 1 (160 cps) followed by a 0.15-second gap; a 0.5-second bust of tone 7 (256 cps) followed by a 0.15-second gap; and a 0.5-second burst of tone 9 (301.18 cps). There would be a time interval of 3.2 seconds before the next code was transmitted.

The coded signal for a 4-digit, or 4-reed, system is made up in a similar manner. In this case four bursts of tones are transmitted. In the 4-reed system the length of the tone duration, the gap interval, and the guard band are somewhat different from those of the 3-reed system. The 4-reed system is more likely to be used in city-wide paging systems where traffic may be a problem. To ensure the maximum amount of traffic within the capabilities of the system, the time required to transmit a code group is held to a minimum. In this case the coded signal is 1.4 seconds in duration with a guard time of 2.5 seconds between code groups. With this timing, approximately 15 codes per minute can be transmitted. In the 3-reed system a maximum of 12 codes per minute can be transmitted.

As mentioned previously, the choice of the audio frequencies was dictated by the decoding mechanism in the receiver. A similar situation exists in determining the time intervals in the coded signal, namely, the timing is dictated by the decoder. This will also be discussed in connection with the receiver.

Encoder

The encoder is the heart of the system as it controls the transmitter modulation, generates the proper tones, selects the tones, and transmits them in the proper sequence to the transmitter. A block diagram of the encoder used in the 3-digit system is shown in Fig. 2.

TONE GENERATOR

One of the functions of the encoder is to generate the proper tone frequencies. This is accomplished in the tone generator section of the encoder in the following manner.

The first stage is a crystal-controlled audio-oscillator which operates at a frequency of 20.48 kc ±0.012%. The output from the oscillator, which is sinusoidal, is coupled to the second stage, where the signal is shaped to provide a pulse that has a sharp negative edge. There will be one negative pulse out of the shaper stage for each cycle of oscillator voltage input. The frequency is still 20.48 kc.

The next stages (1 through 7) are identical binary dividers, a common type of plate-coupled bistable multivibrators. Because they are binary dividers, it takes two input pulses to provide one output pulse. With seven of these stages in cascade the dividing chain will divide by two, raised to the seventh power or 128. Thus for an input frequency of 20.48 kc to the first binary divider; the output frequency of the last divider will be 160 cps, which corresponds to the frequency of tone 1.

When the tone 1 frequency has been generated, the next problem is to generate the other eight frequencies or tones. This is accomplished by applying feedback to the proper stage or stages in the binary divider chain. The action of channeling feedback pulses from the output of the dividing chain into any one or more of the stages in the dividing chain is to alter the division factor of the dividing chain.

To develop the frequencies required for tones 2 through 9, feedback is applied to as many as four stages simultaneously. Considering the first five stages of the dividing chain, the division factor with no feedback will be 32. With feedback applied to as many as four stages, any division factor between 17 and 32 can be obtained. The over-all division factor can be determined by multiplying this division factor by four. Table I shows the required over-all division factors necessary to generate the required nine tones and a list of the stages to which feedback must be applied to generate these tones.

The output from the last divider will then be any of the nine tones, depending on the division factor. This output signal is applied to the output stage which in turn feeds the signal to the modulator stage in the transmitter.

The reset (feedback) pulse is generated by taking an output from the sixth binary stage and coupling it into a reset pulse generator. The reset pulse generator differentiates and amplifies the input

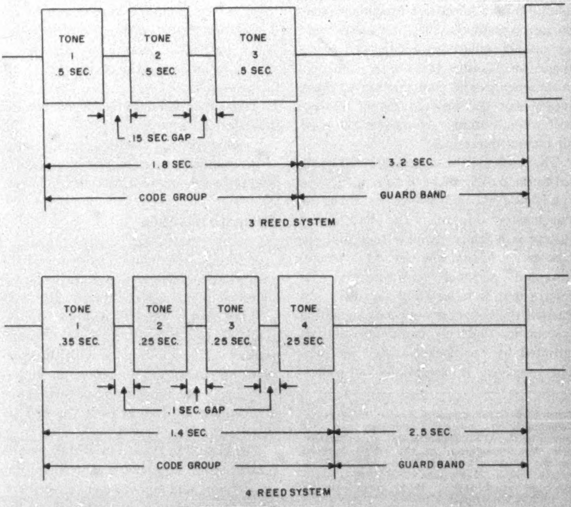

Fig. 1. Modulating signals employed in 3-digit and 4-digit systems

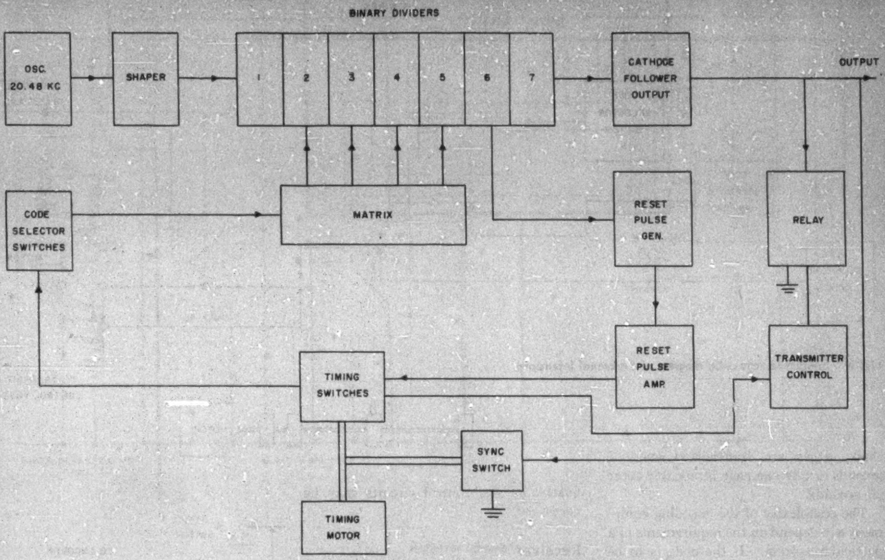

Fig. 2. Encoder block diagram used in 3-digit system

pulse. The output from the reset pulse generator, which is a sharp negative pulse, is further amplified in the reset pulse amplifier stage and channeled through the interrupter, the code selector switches, and the neon bulb matrix, to apply feedback to the proper binary stages.

The reset pulse amplifier was necessary to assure that the reset pulse would be of sufficient amplitude to apply feedback to all four stages when tone 9 was required. The position of the code selector switches determines to which stage the feedback is applied, and therefore determines the frequency of the tone generated. The matrix converts the settings of the code selector switches, which are in decimal notation, into an equivalent binary form. Neon bulbs are employed in the matrix since they are essentially open circuits unless ionized. The ionization time delays the reset pulse the required amount of time.

INTERRUPTER

The tones are sequenced properly with the aid of a timing motor and a combination of switches. The complete assembly is referred to as an interrupter. A simplified schematic diagram of a 1-channel interrupter is shown in Fig. 3.

The timing motor drives a shaft on which are mounted three cams which activate three spring-type transfer switches. The three switches provide a path to the code selector switches for the reset pulses. The settings of the code selector switches will determine the frequency of the tones transmitted.

After the code of the receiver to be paged is set up on selector switches, the code bank switch is turned on. This starts the interrupter motor and cams rotating. In rotating, the cams will activate their associated switches. The design and adjustments of the cams are such that the first switch will be on the off-normal position for the full duration of the code group. The second switch will be in the off-normal position for the last two thirds of the code group time, and the third switch will be in the off-normal position for the last third of the code group time. Thus, in operation the reset pulse will be channeled through the first, second, and third code selector switches in that order as the cams rotate. This action will result in three sequential tones being generated.

The gaps are inserted by utilizing an additional cam and switch. This switch has a single set of contacts which, in the normally closed position, ground the output of the encoder. The cam has three successive notches and, when the arm of the switch falls into one of the notches, the ground on the output of the encoder is removed. By properly synchronizing all of the cams the output of the encoder for a 3-digit system will be as shown in Fig. 1.

The encoder also provides the necessary control of the transmitter. When the first switch in the interrupter is in the off-normal position, the grid of the transmitter control tube is removed from ground and the tube is allowed to conduct. This tube controls a relay which has several sets of contacts: one set controls the transmitter carrier; an additional set controls the output from the encoder. The transmitter carrier will be on only when a code group is being transmitted. As long as the code bank switch in the encoder is in the ON position the timing motor will continue to rotate and the code will be transmitted once for each revolution of the cams.

ENCODER VARIATIONS

The operation of a single-channel encoder has been described. In the encoder for an industrial system four channels are available. This requires that there be four sets of code selector switches and four sets of switches in the interrupter circuitry. The timing motor runs at a speed of 3 rpm. Since the cam shaft is direct-driven from the motor

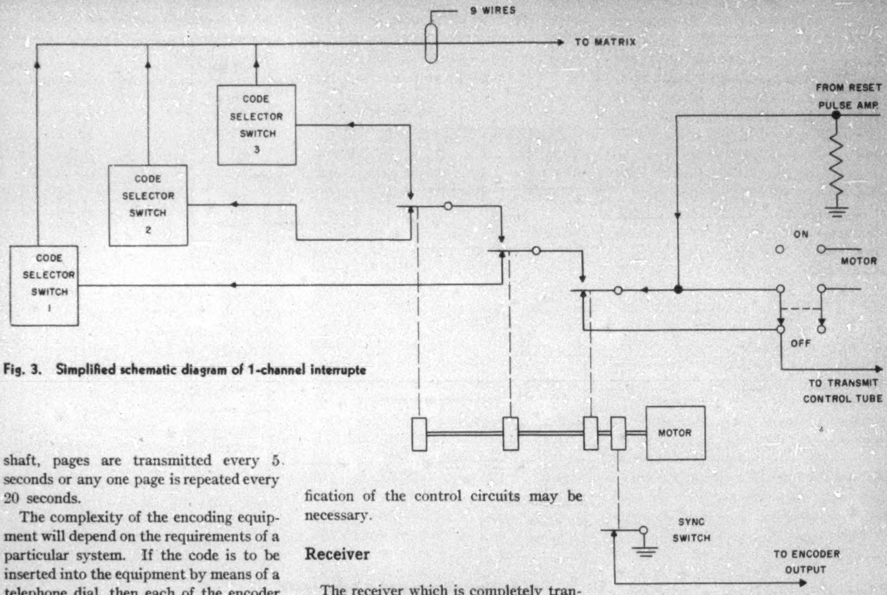

Fig. 3. Simplified schematic diagram of 1-channel interrupte

shaft, pages are transmitted every 5 seconds or any one page is repeated every 20 seconds.

The complexity of the encoding equipment will depend on the requirements of a particular system. If the code is to be inserted into the equipment by means of a telephone dial, then each of the encoder switches will have to be replaced by a register and its associated circuitry. The number of channels required will also make the circuitry more or less complex. In any event, the operations described will have to be performed in one manner or another to generate the required signal.

Transmitter

The ouptut from the encoder is fed over a connecting cable to the transmitter. The transmitter must be capable of being amplitude-modulated with frequencies ranging from 160 to 301 cps. The transmitter must also meet the Federal Communications Commission's requirements, which will vary, depending on the service for which the system is to be licensed.

At present, transmitters with 3, 5, and 30 watts of power input to the final amplifier stage are available for use in the industrial system. The encoder has the necessary facilities for controlling the power to the transmitter and the transmitter carrier. Provision is also made for aurally monitoring the modulation to the transmitter.

Where increased coverage is necessary, transmitters with greater power output are required. Commercial transmitters which are readily available can be used in this application. However, some modification of the control circuits may be necessary.

Receiver

The receiver which is completely transistorized weighs only 7 ounces and is powered by three mercury cells. The receiver case is made of a material having good high-frequency characteristics and has a clip which will hold the unit securely in the pocket or on the belt. Operation of the receiver is limited to a simple OFF-ON switch to apply power and a momentary contact switch to squelch the audio tone when the receiver is signalled.

The transistorized receiver is a 4-transistor unit. The transistors are used in a super-regenerative detector stage, a 2-stage audio amplifier and a "buzzer" or audio-oscillator stage. Also included in the receiver is a decoder which gives each receiver its individuality. The schematic for the receiver is shown in Fig. 4.

Super-regenerative Detector

Used in this stage is a *2N/346* surface barrier transistor. R-f energy is introduced into the receiver via the tank circuit comprised on *L-2* (the antenna coil), *C-12* and *C-13*. Because of the effects of body capacity and the changes in collector capacity from transistor to transistor a large capacitance-to-inductance ratio is used.

R-f oscillations are generated by returning to the emitter a portion of the in-phase voltage developed across the tank circuit. The inductance in the emitter circuit provides a low d-c path to ground for the emitter. The emitter inductance also provides a parallel resonant circuit with *C-11*. This circuit is tuned so that in effect it acts capacitively. Thus, across the antenna circuit there is a capacitive voltage divider, comprised of the effective capacity in the emitter circuit and the collector to emitter capacity of the transistor. The amplitude and phase of the feedback are controlled by the tuning of the emitter circuit.

The transistor is forward-biased by returning the base back to the negative side of the battery through *R-10*. When the transistor begins to oscillate, the positive excursions of the emitter will allow the charge on *C-10* to increase until the transistor is cut off. At this time the oscillations will stop and remain stopped until the capacitor discharges to a point where oscillations can again be sustained. The *R-C* time constant in the base circuit will determine the discharge time.

The point at which oscillations start is also a function of the strength of the r-f signal. The greater the signal strength, the sooner the oscillations will start. Thus for a given signal strength the quench frequency or the frequency at which the oscillations build up and decay will be a function of the time constant in the base circuit. Also, for a given time constant in the base circuit the quench

Vol.
Pt. 1
195

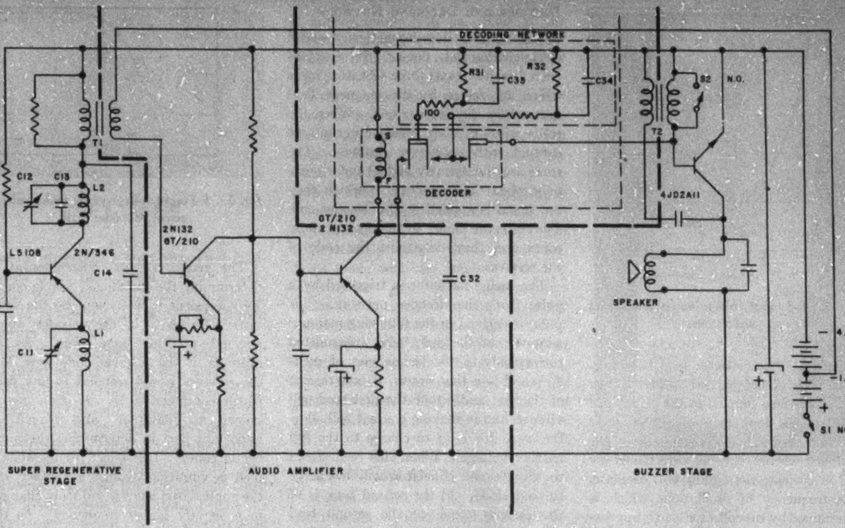

Fig. 4. Receiver schematic

frequency will increase as the signal strength increases.

If attenuation of the audio frequencies is to be avoided, the quench frequency should be greater than ten times the highest audio frequency. Another important factor in selecting the quench frequency is the selectivity. A low quench frequency will result in greater selectivity. The resistor in the base circuit was selected to provide an operating point where the stability and sensitivity were good. The capacitor in the base circuit was therefore selected to provide the proper quench frequency. A quench frequency of approximately 10 kc is employed, which is well above the maximum audio frequency used in the system.

The tuning of the emitter circuit will also have an effect on the quench frequency, sensitivity, and selectivity. Optimum adjustment of the emitter circuit occurs when there is maximum noise output from the detector. After adjusting the receiver for the maximum noise output, the antenna circuit is tuned for the proper frequency of operation. The receivers are pretuned at the factory, thereby eliminating the need for customer tuning.

If the signal varies at an audio rate the collector current will vary at an audio rate. This variation in collector current is detected in the collector circuit of the superregenerative stage. The primary of *T-1* and *C-14* are tuned at the low end of the audio band of frequencies used in the system. The change in collector current develops an audio voltage, across the primary of *T-1*, which is coupled through the transformer to the audio amplifier stage.

Audio Amplifier

The transformer *T-1* matches the collector impedance of the r-f stage to the input impedance of the audio amplifier. Two stages of audio amplification are used, both employing type *2N/132* or *GT/210* p-n-p transistors. Stabilization of the operating point is important and necessary in these stages to prevent an increase in collector current due to temperature variations, and to compensate for variations in transistor parameters between different transistors. Stabilization is accomplished by the use of a battery tap for the base bias of the first stage and by using larger emitter resistors in the emitter circuits of each of the stages. The emitters are bypassed with electrolytic capacitors to prevent degeneration of the audio signal.

The gain of the audio amplifier is controlled by a variable resistor in series with the bypass capacitor in the emitter circuit of the first stage. This method of control allows the audio-frequency gain to be varied without affecting the d-c operating point.

The collector of the first audio stage is direct-coupled to the base of the second stage. The collector load of the second stage is the coil in the decoder. This coil is tuned to the high end of the audio-frequency band by means of capacitor *C-32*. In effect, the tuning of *T-1* and the decoder coil results in a stagger-tuned amplifier which peaks at approximately 256 cps (tone 7).

The operation of the audio amplifier is such that the output is limited on a strong signal. The maximum output is approximately 2.3 volts, rms, on tone 7 with a strong input signal to the antenna. The over-all gain of the audio amplifier is approximately 50 db (decibels).

Audio-Oscillator or Buzzer Stage

The audio-oscillator stage employs an n-p-n type of transistor which is a selected *2N/169*. Referring to the schematic, it is seen that there is no bias applied to the base circuit of this stage. The emitter and the base of the transistor are tied together through the low resistance of the secondary of *T-2*. With no bias, the transistor is practically cutoff. In fact the current is less than 10 μa (micro-

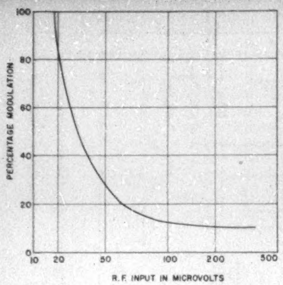

Fig. 5. R-f input voltage versus percentage modulation

amperes). The collector load is a magnetic type of hearing-aid speaker. The collector is also coupled to the primary of *T-2*. If the loop gain of the stage is greater than one and the phase of the feedback to the base as determined by *T-2* is correct, the circuit will oscillate. The frequency of oscillations which is determined by the collector load is approximately 1,500 cps. However, under the stated biasing conditions, the loop gain will be less than one and the oscillator will be blocked. This is the normal operating condition.

If a positive pulse should appear on the base of this stage, it will be amplified and returned in phase to the base via *T-2*. If the pulse is of sufficient amplitude, the instantaneous gain to the transistor will reach such a value that the loop gain will be greater than one. At this time, the transistor will be driven into oscillation and will remain in oscillation. Once the oscillations have started, they may be stopped by depressing a momentary contact switch which is across the secondary of *T-2*. This automatically resets the oscillator and returns it to the stand-by condition to await the next positive pulse. The positive pulse to trigger the oscillator is derived from the decoding network when the correct code has been received.

In the blocked condition this stage will draw less than 10 μa; however, in the oscillating condition the stage will draw up to 6 ma (milliamperes). The current drawn varies from transistor to transistor since the operating point of each of the transistors may vary. To ensure that the oscillator will not be self-triggering at high temperatures, the transistor is selected for low-leakage current. To ensure that the transistor will oscillate properly when it is triggered, it is also selected for the proper beta characteristic.

DECODER AND DECODING NETWORK

The decoder is a hermetically sealed electromechanical device. It contains (in a 3-reed system) three vibrating reeds which are driven by the magnetic field induced by the decoder coil. When the reeds vibrate, they make intermittent contact with stationary contacts. The reeds are of extremely high Q and vibrate only when the frequency to which they are tuned is applied to the decoder coil. The reeds are tuned to the desired audio tones and they determine the code of the receiver.

The audio oscillator is triggered by a pulse from the decoder network. The pulse is derived in the following manner: assume that the code being transmitted corresponds to the frequencies of reeds 1, 2, and 3 in that order. Upon receipt of the first audio tone the first reed will vibrate, and in making contact will allow the capacitor *C-33* to charge to the full battery voltage. When this reed ceases to vibrate the capacitor will discharge through *R-31*. If the second tone is of the correct frequency the second reed will vibrate and hit its contact. When this occurs, the charge on *C-33* will transfer to *C-34*. The capacitor *C-34* will also discharge after the second reed ceases to make contact. If the third tone is the correct one, the third reed on making contact will transfer the remaining charge to the base of the audio oscillator, causing it to oscillate. The individual reeds will vibrate and make contact at any time that their particular frequency is received. However, the tones must be in the proper sequence to transfer a positive pulse to the buzzer stage.

As mentioned earlier, the nine audio frequencies used were determined by the decoder. To eliminate any harmonic problems in connection with the reed response, the nine audio frequencies utilized lie within a single octave. The exact frequencies chosen represent a compromise of several considerations.

As the frequency is increased, reed sensitivity decreases and more driving power is required to achieve a given deflection amplitude. Also, as the frequency decreases the response time of the reed increases and the time required for the reed to reach a given deflection amplitude increases. The natural frequency of a vibrating reed fixed at one end varies inversely as the square of its length; therefore the physical size of the reed had to be considered. The compromise resulted in selecting a group of frequencies ranging from 160 to 301 cps.

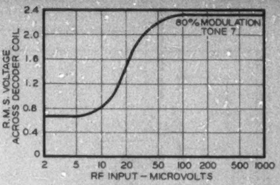

Fig. 6. R-f input voltage versus audio voltage across decoder coil

The reeds are also instrumental in determining the number of usable codes. Two adjacent tones cannot be the same since both reeds in the decoder would respond at the same time. As an example, if the receiver code were 115, the receiver would respond to any code which contained a 15. A phenomenon known as "hang-on" also played an important part in determining the number of codes. This effect occurs when a reed is vibrating against a contact and the applied frequency is suddenly changed to a slightly higher frequency. As the reed vibrates against the contact, its effective length is shortened and therefore its resonant frequency increases. At the same time the Q of the reed decreases. If the applied frequency is suddenly changed to a slightly higher frequency, the reed will continue to vibrate. The end result would be false triggering of the reed. This will be more evident in the following example. If the code 124 is being transmitted, the receiver with code 124 will respond in the normal fashion. At the same time the receiver with the code 214 could respond due to the "hang-on" of the middle reed. To alleviate this condition codes with ad-

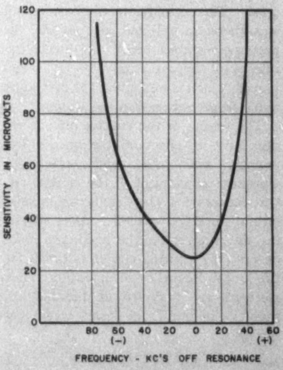

Fig. 7. Selectivity

Vol.
Pt. 1
195

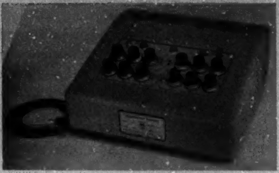

Fig. 8. Encoder

jacent descending numbers are eliminated from the system. These effects limit the number of usable codes in a 3-reed system to 455, and in the 4-reed system to 3,235.

The time intervals of the coded signal as shown in Fig. 1 were also determined by the reeds. The time duration of the tones must be long enough to allow the reeds to make contact. Since the reeds have Q's in the order of 200 they will not make contact immediately. The gaps between the tones are inserted to allow the reeds to decay somewhat before the next tone is applied to the decoder coil. With the gaps the hang-on effect of the reeds is less likely to occur. The guard time is necessary to allow the capacitors in the decoding network to discharge before the next call is received.

Power Supply

The receiver is powered by a 4-volt battery made up of three mercury cells connected in series. A tap on the battery provides the bias for the first audio stage. With the power switch in the OFF position the battery drain is approximately 10 μa. With the power switch on and the buzzer off the battery drain is approximately 750 μa. This is the normal operating current. The current drain with the buzzer on is approximately 6 μa.

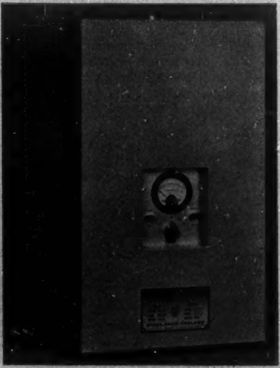

Fig. 9. Transmitter

With a normally operating current drain of less than one ma the battery life is approximately 950 hours. The audio-oscillator stage draws current only when the receiver is triggered by the correct code and, since the triggering is done intermittently, the additional current drawn by the audio oscillator will not seriously effect the battery life. Tests made with the receiver operating continuously and with various duty cycles have resulted in approximately the same operating battery life.

A new battery will have a voltage slightly greater than the 4 volts but, after the first 50 hours of operation, the battery voltage will decrease to 4 volts and remain at 4 for 90% to 95% of its life.

Receiver Variations

Several models of the receiver which differ in the number of reeds in the decoder and the operating frequency are currently in production. Three-reed or 4-reed receivers differ in the decoder and the decoding network constants. Receivers operating at 27 or 35 mc (megacycles) differ in the antenna coil and the constants in the base circuit of the *2N/346*.

Receiver Testing and Performance

The receivers are tested by inserting them in an upright position in the center of a loop. The loop is fed directly from an r-f signal generator which is amplitude-modulated with a signal from a tone-sequence generator. The receivers are required to trigger with a signal of approximately 50 μvolts into the loop. The receivers are also checked with adjacent and reverse codes to ensure that they will not false-trigger in the field.

Typical performance curves of 27-mc 3-reed receivers are shown in Figs. 5 through 7. Fig. 5 shows the required signal into the loop to trigger the receiver for various percentages of modulation. With 100% modulation as the reference or zero-db point, a modulation percentage of only 60% will result in a 2-db loss in receiver sensitivity.

The audio voltage developed across the decoder coil for various amounts of signal into the loop is shown in Fig. 6. This curve shows the limiting action of the receiver for input signals above 50 μvolts.

The selectivity of the receiver is shown in Fig. 7. The average 6-db bandwidth is approximately 75 kc for the 27-mc receivers. The 35-mc receivers have a bandwidth of approximately 45 kc.

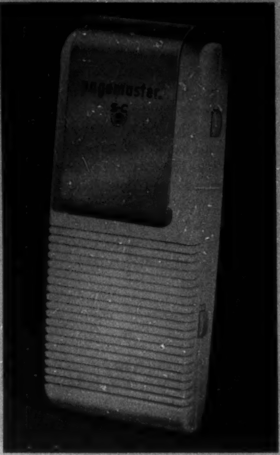

Fig. 10. Receiver

Industrial Equipment

The equipment used in industrial and hospital paging systems is shown in Figs. 8 through 10. The encoder is designed in an attractive case for location near the paging operator. It is 14 inches wide, 14 inches deep, and 7 inches high. The encoder has a self-contained power source, a transmitter remote control switch and a carrier monitor light. There are 4 code group switches and 12 tone-selecting knobs, three for each of the code groups, which can be set up simultaneously. All vacuum-tube circuits with the exception of the transmitter control circuit and the reset pulse amplifier are of the plug-in type. This encoder is capable of generating the codes required to service 455 selective receivers.

The transmitter pictured is the 30-watt version. The 5-watt unit is of the same general construction but somewhat smaller in size. The 5-watt transmitter is $16^{1}/_{4}$ inches high, $8^{1}/_{4}$ inches wide, and 7 inches deep. The transmitters, which are designed for wall mounting, can be remotely located and controlled from the encoder.

The receiver shown in $2^{3}/_{4}$ inches wide, $5^{3}/_{4}$ inches long, and 1 inch deep. The case which is styled for easy insertion into the pocket is ivory-colored with a gold clip for securing the receiver in the pocket or on the belt. A twist-lock cap over the battery compartment allows the battery to be easily replaced.

At present, a majority of the industrial systems in operation are operating at 27.255 mc in the citizens radio band. The range or coverage in any given installation is dependent on such factors as the antenna height and terrain conditions. In buildings the coverage depends on the type, layout, and construction of the building. Each installation has specific requirements and it is difficult to make broad statements as to exact coverage without having made a survey. However in nearly all installations where one building or a group of buildings in the same area are to be covered, the 5-watt transmitter will provide the necessary coverage. Where increased coverage is required the 30-watt unit is available.

Conclusions

The development of the Pagemaster system is a further step toward improving communication and paging operations, and offers many advantages over other types of paging systems.

The system can be easily and economically installed. A system can be started with a few receivers, and expanded at any time as the need arises without any additional changes in the base station equipment. The paging operation is quiet, personal, and selective. The system provides instant contact with key personnel.

City-Wide Personal Signaling at Allentown-Bethlehem, Pa.

C. R. KRAUS
MEMBER AIEE

IN THE Allentown-Bethlehem area of Pennsylvania, the strange sound of a low whistle issuing from the coat pocket of a pedestrian (who will, on hearing it, probably seek the nearest telephone and dial a number) might be mystifying to the uninitiated. But to the pedestrian from whose pocket the whistle actually came, it represents a new Bell system telephone service that for some time has been functioning in this area.

Known as Personal Signaling Service, this new development in the telephone art is consistent with one of the basic objectives in furnishing complete telephone service, i.e., making certain that the maximum number of calls are completed and that the calling party reaches the person with whom he wishes to speak.

Need for Signaling Service

To attain such a dual objective successfully obviously suggests the need for reaching the called party when he is not in the immediate vicinity of his telephone. One effort in this direction has resulted in the provision of extension bells which the telephone company has been furnishing for many years. Others have resulted in the provision of code calling or paging systems by means of which, through audible tones or voice, the wanted person may be called to the telephone if he is anywhere on the premises. Such devices have definite limitations, however, and they are useless when the desired individual is away from his premises. Selective signaling service to receivers mounted in vehicles is another useful Bell system communications device directed toward this same objective.

Radio paging pocket-carried receivers which are signaled on a nonselective basis by voice operation also offer possibilities and have a definite field of use since with them the transmission of messages as well is possible. Unfortunately, however, these pocket-carried receivers also have several limitations. First, it is required that the user take certain action at rather frequent intervals; he must turn on his receiver and listen through a cycle of codes or messages to find out whether or not he is being paged. Not only is the individual inconvenienced but also, and of much greater significance, he is unavailable during the period when he is not listening to his receiver. Second, there is a limit to the number of customers who can be served over a single channel. This limit is the natural consequence of the number of times a particular code or message must be repeated in order that the individual being paged will hear it. As the number of customers to be served increases and the number of messages to be put on the air simultaneously becomes greater, the length of the listening cycle increases proportionately.

By contrast, the user of the selective signaling system hears only his own signal when it is sounded over his pocket-carried receiver. No listening cycle is involved; the signal is received at virtually the same time it is transmitted. The service also has an advantage over the vehicular selective signaling service because it eliminates the requirement that the user remain in the proximity of his vehicle. The advantage of selective signaling to pocket-carried receivers, therefore, is to increase substantially the ability of calling parties to communicate with the individual carrying the receiver. As a result, the system is ideally suited to doctors, lawyers, and other professional men, as well as to many types of businesses which must maintain fast, certain, and economical contact with their personnel.

How the Service Functions

A brief, general description of how the service functions may best be understood by reference to Fig. 1. Assuming that the customer is wanted, that he presumably is somewhere in the area, and that he has with him his pocket-carried signaling receiver, the steps in the operation of the service are as follows:

Step 1. By prearrangement, his secretary, or some other person, dials a special number and reaches the telephone company's signaling operator. The secretary advises the operator of the number to be signaled. This is a 4-digit number.

Step 2. The signaling operator "dials" the 4-digit number. She also records the information for billing purposes.

Step 3. Four voice-frequency tones are transmitted by the radio transmitters over the 35-mc (megacycle) channel.

Step 4. The customer's pocket receiver

Paper 58-813, recommended by the AIEE Radio Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, N. Y., June 22–27, 1958. Manuscript submitted March 31, 1958; made available for printing July 2, 1958.

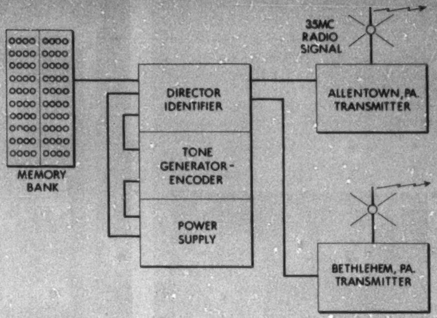

Fig. 2 (right). Block diagram of control equipment

is actuated by the four voice-frequency tones and the customer receives the signal, in the form of a pleasant whistle.

Step 5. On being alerted, the customer presses the cutoff button to stop the whistle and calls, by prearrangement, his office or some other point from the nearest telephone.

Inception

The telephone company offers three types of mobile telephone service. The first of these, General Mobile Service, provides for 2-way telephone communication between a mobile unit within range of a radio base station and any wire telephone or between two such mobile units. The second, Dispatching Service, provides for 2-way telephone conversation between a designated dispatching office of a customer in a mobile service area and a designated mobile unit of the customer within the range of the radio base station. The third, Selective Signaling Service, is a 1-way service from any wire telephone located in a mobile service area to a mobile unit equipped for such service within range of the land radio station serving that area.

Selective Signaling Service is furnished only to receivers mounted in vehicles. The Allentown-Bethlehem Personal Signaling Service is an extension of this same type of service to pocket-carried receivers.

Comparison of Voice, Private, and City-Wide Systems

In any discussion of this new selective type of service, there is the obvious question of how it fits in with existing voice paging services and other types of selective signaling systems which stem from the basic concept of a modulating system for transmitting a number of voice-frequency tones and a receiver which is individually sensitive to a specific succession of certain tones.

The voice system, of course, satisfies a definite need and fulfills requirements so far as the transmission of a message is concerned. However, with a large number of receivers in a system, the voice system can be inadequate because of the large amount of voice traffic. By contrast, inherent in a selective signaling system is the capacity for handling a large number of customers. For example, the system installed in the Allentown-Bethlehem area is a city-wide signaling system with a capacity of approximately 3,200 receivers, any one of which can be signaled. This means that the system capacity is sufficient to make the service available to all prospective users in a sizable service area.

There are many places where a system with a capacity for a smaller number of receivers and with a fewer number of digits to be transmitted is suitable, such as individual buildings, manufacturing plants, hospitals, and similar locations. A description of these simpler private systems, together with information on the fundamental modulating system and the details of the transistorized receiver with its selective mechanism, is covered in a companion paper elsewhere in this issue.[1]

Objectives

The objectives of the experimental installation of personal signaling service in the Allentown-Bethlehem area are in two categories, commercial and technical. Commercially, the area was selected as a good location to explore the possibilities of the field of use of a city-wide system. It was installed to determine the types and the number of customers who would find a use for the service, as well as the amount of use which the customers would make of the service. Fundamentally, the question to be determined is whether this sort of a system will find sufficient customer acceptance to justify its existence.

Technically, the objectives were to determine the quality of performance of the equipment components of the system and to obtain sufficient experience in service to formulate basic operational needs.

Description of the System

The Allentown-Bethlehem system consists of two radio base station transmitters arranged to signal pocket-carried receivers selectively. In addition to the transmitters, control equipment as shown in Fig. 2 is part of the system. A device called a memory bank is installed at the switchboard and the operator selects the voice tones to be transmitted by setting

Fig. 3. Transmitter

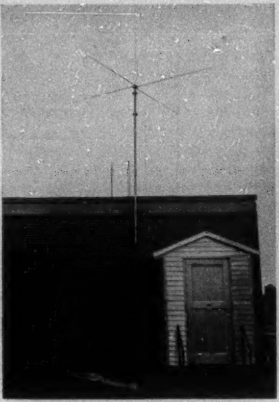

Fig. 4. Transmitter housing and antenna

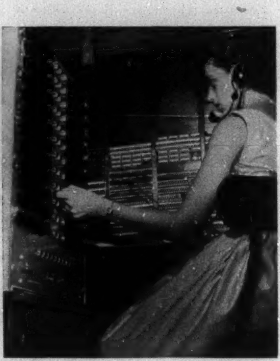

Fig. 5. Memory bank

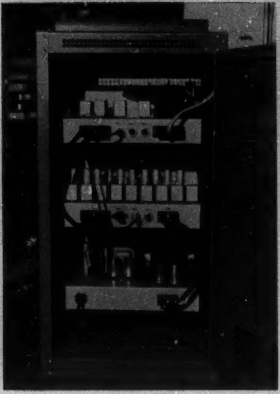

Fig. 6. Tone generator and associated equipment

Top—Director unit
Center—Tone generating unit
Bottom—Power supply

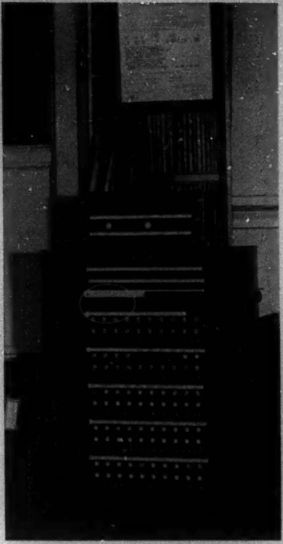

Fig. 7. Other control equipment

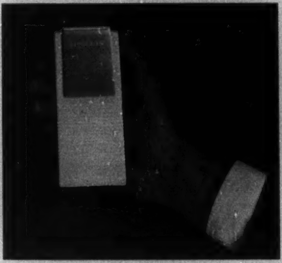

Fig. 8. Receiver

dials on the memory bank. The tone generators and other equipment modulate the radio-frequency carrier and perform other necessary functions.

The amplitude modulation transmitters (see Fig. 3) are Erco Model *301TA*, having an output of about 250 watts and designed to operate in the 30-to-40-mc band. They are operated simultaneously, one at 35.3378 mc and one at 35.3412 mc. This separation of 3.4 kc between transmitter frequencies removes the beat note from the signaling tone band. The antenna structure associated with each transmitter is of standard design consisting of an Andrew type *900* folded unipole antenna. Fig. 4 shows one transmitter housing and antenna on the roof of the Allentown telephone central office building. The other transmitter is located in the Bethlehem telephone central office building.

CONTROL EQUIPMENT

The memory bank, shown in Fig. 5, is part of the control equipment, and consists of a panel containing dials for selecting and storing codes to be transmitted. A maximum of 24 different codes may be selected at one time. The codes selected are stored and each is transmitted three times sequentially by means of a self-contained, electrically operated scanning mechanism. The scanning is continued as long as codes are present in the memory bank. When the scanning is stopped, station identification is transmitted and both transmitters are shut down.

Fig. 6 shows the tone generator and associated equipment, mounted in the equipment room on the second floor of the Allentown central office. The tone-generating unit makes available nine different audio frequencies, quartz-crystal controlled, in the range of 160–300 cycles. The frequencies are selected in groups of four tones for individual calling codes. The four tones comprising a code are transmitted sequentially and require approximately 2 seconds for transmission. With this signaling arrangement, it is possible to select one individual pocket-carried radio receiver out of a group of over 3,200 such receivers.

The director unit, also shown in Fig. 6, controls the radio transmitters, and arranges for the scanning of the codes in the memory bank and for transmission of the codes to the radio transmitters. Station identification by international Morse Code is automatically transmitted over one of the transmitters once every half-hour during continuous transmission. In addition, station identification is automatically transmitted immediately prior to any period during which both transmitters have been shut down. The radio transmitters are remotely controlled by means of a direct voltage applied over wire lines.

Vol.
Pt. 1
195

Other control equipment consists of two keys and two lamps installed in the test center on the fourth floor of the Allentown central office. One key is associated with each transmitter. The keys are normally in the ON position. When they are turned to the OFF position, they prevent the transmitters from being placed on the air. The lamps indicate when either of the transmitters is turned off; see Fig. 7.

RECEIVER

The receiver shown in Fig. 8, is of a transistorized, superregenerative type and weighs about 8 ounces. It includes an electromechanical selective mechanism consisting of four reeds which respond to individual frequencies and a hearing-aid type of speaker for signaling.[1]

COVERAGE AND TRANSMISSION DESIGN

A discussion of the transmission design and a review of the coverage results, together with certain important data on shielding by buildings at both 30-to-40 and 150 mc, will be found in a companion paper.[2]

Operating Experience

As the result of more than 10 months of operation, it is concluded that

1. The service fulfills a need, as evidenced by extensive usage and a steady growth in the number of customers.
2. The maintenance problems, particularly concerning the receiver are somewhat greater than expected, but further work is in progress and improvement is anticipated.
3. The size, shape, and weight of the receiver might be improved.
4. There are some service problems in regard to handling equipment outages.

The experiences thus summarized will be of benefit in the further development of the system.

Contemplated Improvements

A number of improvements in operation are contemplated for the service, some of which are as follows:

1. Dial operation at the switchboard rather than manual setting of the four dials for each call.
2. Use of existing mobile 35-mc systems with signal selective calls interposed between conversations.[2]
3. The use of suitable frequency-modulation personal receivers having a selective signaling arrangement: the use of the frequency-modulation stations now in existence awaits the availability of these receivers.

Conclusion

Personal Signaling Service has established itself in the Allentown-Bethlehem area as an essential part of a telephone service that is ever expanding in scope. From an operational standpoint, the experiment disclosed areas in which improvement is desirable. Some development work remains to be done, therefore, in order that the service may merit a high degree of over-all customer acceptance.

Systems Engineering of Personal Radio Signaling Systems

WALTER STRACK
NONMEMBER AIEE

IN two other papers Kraus[1] and Young[2] describe in some detail the operational and equipment features of 35-mc (megacycle) amplitude-modulated systems for providing one-way selective signaling service. This paper covers a number of the problems associated with the planning and evaluation of systems operating in either the 35- or 150-mc range which might be used to provide city-wide coverage. Fig. 1 is a simplified schematic of a signaling system and illustrates three of the major areas to be discussed. These areas are the pocket receiver, the radio transmission path, and finally the central office facilities.

Evaluation of Pocket Receivers

In order to plan a radio system it is necessary to know the characteristics of the various components. Many of the equipments used in providing one-way signaling service are fairly conventional and their characteristics are either readily available or can easily be determined. Some new problems exist, however, with regard to the pocket-sized radio receivers. First, the antenna in these units is contained within the receiver case and cannot readily be disconnected to facilitate many of the usual measurements. In the case of the Stromberg-Carlson receiver, the antenna is actually a portion of the tuned circuit in the superregenerative detector and cannot be disconnected without disrupting the operation of the set. The second consideration is that these receivers will normally be operated in close proximity to the user's body. This may affect the performance of the unit by modifying the apparent antenna characteristics or shifting the tuning of the receiver. For these reasons, the sensitivity must be determined, initially at least, when the receiver is carried by a person.

In making tests of this type a signal generator was used as the r-f (radio-frequency) source and the audio signaling frequencies were provided by a special "test-tone generator." The output of the signal generator was fed to an outdoor antenna and the output was adjusted to the level required to just trigger the receiver as the user assumed various orientations at a point about 100 feet removed from the antenna. The actual field strength for various settings of the signal generator were determined using conventional measuring equipment.

Tests have shown that sensitivity is a function of where the receiver is carried, on the belt or in a pocket, and also depends to some extent on the type of clothing worn. Sensitivity variations in the order of ±10 db (decibels) have been measured as the user rotated through 360 degrees.

The procedure for determining the sensitivity of the receivers which have speech output rather than selective signaling is somewhat more involved. Historically, the sensitivity of voice equipment is usually measured in terms

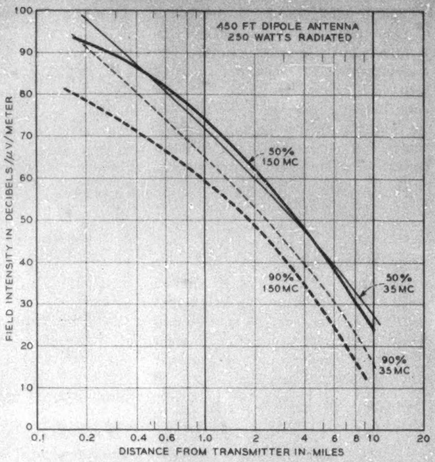

Fig. 3. Field intensity in city streets, 35 and 150 mc

of noise quieting or the r-f level required to produce a given signal-to-noise ratio. The usual arrangement is to bridge a transmission measuring set across the audio output terminals. When this approach was attempted with the pocket receivers, it was found that the meter leads acted as antennas and modified the sensitivity of the receivers in a more or less random fashion depending on the drape of these leads.

One solution to this problem is to use acoustic coupling between the receiver and the measuring set. The output of the miniature receiver speaker can be fed through a length of plastic tubing to a microphone. The output of the microphone is connected to the transmission measuring set thus providing means for measuring either noise quieting or tone-to-noise ratios. This arrangement is illustrated in Fig. 2.

These techniques were found to be satisfactory for original laboratory investigation of receivers of this type. They are not satisfactory, however, from the standpoint of the technician who must maintain a large number of the units on a routine basis. To facilitate this type of work, jigs have been devised to mount the receiver in a fixed position. The r-f signal is introduced using either inductive or capacitive coupling from a near-by lop, probe, or the like. This whole arrangement can be placed in a shielded box or room to exclude extraneous signals and can be calibrated to give sensitivity data of the type available when the more elaborate out-of-door setup is employed.

Transmission Considerations

To ensure satisfactory transmission performance of a radio system the following simple relationship must exist: transmitter output power−path loss=field intensity≥receiver sensitivity.

Essentially, this states that whenever the field intensity is equal to or greater than the sensitivity of the receiver, a satisfactory grade of service will be provided. In order to determine the useful range of the system, one is concerned with the relationship between field intensity and the physical separation between the transmitter and the receiver.

A considerable quantity of data on path loss has been accumulated over the last few years as a result of the operation of mobile telephone services at 35 and 150 mc. This information is restricted, however, to those areas into which an automobile might travel. Additional data are required to take into account the loss which might be encountered by a subscriber to a personal signaling system when he enters a shielded area such as a building.

This new information has been obtained in such a way that performance within buildings can be predicted by adding a factor, the building loss factor, to the earlier data on field intensity in city streets.

Field Intensity in City Streets

Fig. 3 illustrates some of the data on field intensity in city streets at 35 and 150 mc which has been obtained in the New York City area.[3]

Because of the wide fluctuations which exist as a result of the many obstructions in the path, it was necessary to consider not only the median values (curves labeled 50%) but also the distribution of the radio field strength. The lower curves in Fig. 3 represent the minimum field intensity that can be expected in 90% of the cases at a given distance from the transmitter. The curves shown represent many hundreds of samples of signal strength. It is of interest to note that the median field intensity at 35 and 150 mc is nearly equal. However, variations in level in city streets are somewhat greater at the higher frequency as indicated by the spread between the 50% and 90% curves.

Building Loss Factor

It was anticipated that the amount of loss introduced by a building would be

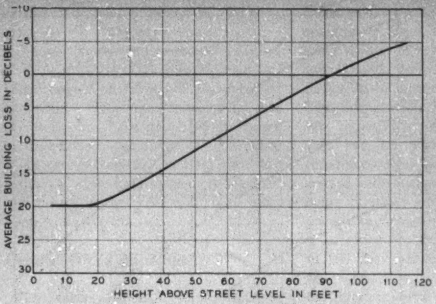

Fig. 4. Building loss versus height above street level

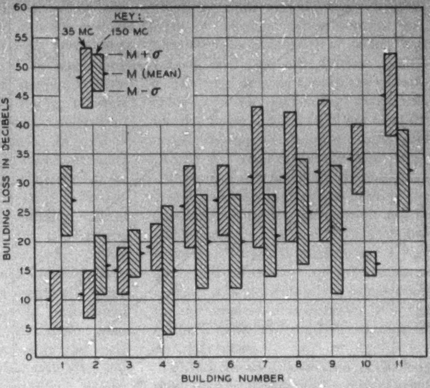

Fig. 5 (right). Measured loss in various buildings in a large city

a function of the type of construction. For this reason, tests were made in a number of buildings, total of 11, having obviously different types of architecture. A number of these had large areas of glass on the lower floors while others used older construction techniques and had fairly thick walls of brick, concrete, etc., and employed structural steel framework.

Preliminary testing in a few buildings showed that the weakest signals, and therefore the greatest path losses, were experienced on the street-level floors of buildings (excluding the basements). An example of the variation in loss on various floors of a building is shown in Fig. 4.

Any system then which will provide adequate service on the street-level floor of a building can thus be expected to be completely adequate on upper floors. Qualitatively, this seems reasonable since the shadowing effect of surrounding buildings decreases as one moves up in a building.

For this reason the bulk of the data on building loss was taken on the street-level floors. Portable field intensity equipment which had adequate selectivity to reject signals on adjacent frequencies was employed to measure the field intensity produced by standard 250-watt mobile telephone transmitters. The number of measurements taken varied from building to building depending on the amount of floor space and the complexity of the floor plan. Measurements were also made in the streets adjacent to each of the buildings. The difference between the median field intensity in the street and the field intensity on the main floor has been called the building loss.

In general, the variations in field strength within a building tended to follow a logarithmic normal distribution. It was possible, therefore, to express building loss in terms of a median value and the standard deviation.

A summary of the results for the 11 buildings is shown in Fig. 5.

It was found that in certain cases a qualitative prediction might be made concerning the losses based on the architectural characteristics of a building. For example, buildings 2, 3, and 4, which have losses well below the average, had high ceilings and appreciable areas of glass. Building 11 which had low ceilings and small windows has a rather high loss.

Unfortunately, such guesses do not always hold true. Building 8 exhibited high loss at both 35 and 150 mc in spite of the fact that it had high ceilings and large window areas.

In order to make use of these data to plan a system, it is necessary to develop a method for describing a group of buildings rather than an individual one. To accomplish this a statistical method was used for combining the characteristics of the 11 buildings so as to obtain a composite picture of the loss introduced by the buildings. This information is shown in Fig. 6. It indicates that the average building loss for this environment is 22 db at 150 mc and 24 db at 35 mc. On the average then, the building losses at 150 mc are slightly less than at 35 mc and as indicated in the figure the variations in loss are also somewhat smaller at the higher frequency. Referring back to Fig. 3, these variations within buildings are just the opposite of those experienced in streets where the low frequency exhibited smaller variations.

Service Range

With information on building loss available, it is possible to estimate the service range possible for systems of the type. Figs. 7 and 8 illustrate the ranges possible at each frequency for varying degrees of service reliability and receiver sensitivity.

For reliabilities in the order of 90%

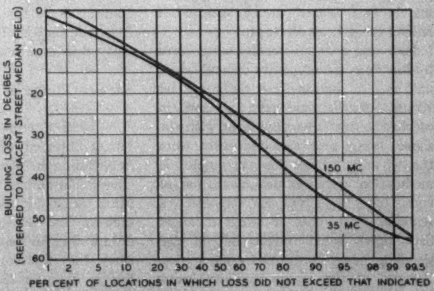

Fig. 6. Variations in building loss, 35 and 150 mc

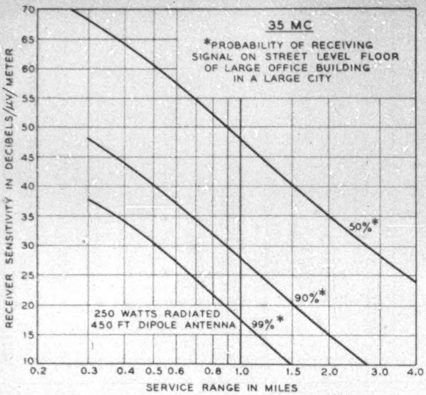

Fig. 7. Estimated service range in a large city, 35 mc

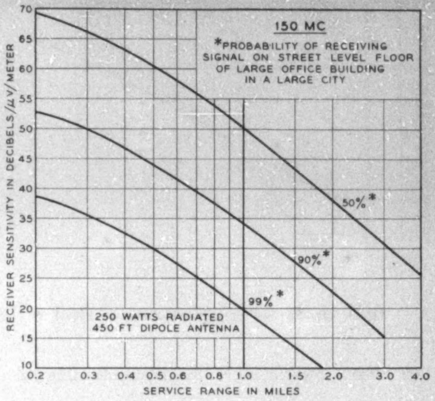

Fig. 8. Estimated service range in a large city, 150 mc

and receiver sensitivities of 100 microvolts per meter (40 db above 1 microvolt per meter), ranges of 0.50 and 0.70 mile are possible at 35 and 150 mc respectively for customers located on the street-level floors of the buildings. On upper floors or in the streets the coverage increases considerably. Based on the data shown in Fig. 3, ranges in the order of 4 miles at 35 mc and 3 miles at 150 mc can be expected in large cities.

Because of the wide variations in loss throughout any one building and because the user may be moving more or less randomly from high- to low-loss areas, a considerable improvement in service can be achieved if the signaling call is transmitted more than once. For example, if the probability of receiving one transmission is 90%, the probability of receiving at least one out of three transmissions is 99.9%. Similarly, the improvement in performance can be stated in terms of an increase in range. By sending the signal three times instead of just once, an increase in range of approximately two to one can be achieved if reliability is held constant.

Increased coverage can also be achieved by installing a multiplicity of land transmitters. As indicated in the paper by Kraus, two transmitters are now in use in the Allentown, Pa., area with the signal being sent simultaneously from the two units. Since this is an amplitude modulation system which makes use of audio tones to accomplish the selective signaling, care must be taken to avoid beat notes which might fall in the signaling band from 160 to 300 cycles. Because of the equipment complexity required to keep the beat note below 160 cycles, the decision in this case was to separate the two transmitter frequencies by approximately 2 kc thus assuring that the resultant beat note would always be above the signaling band. The selectivity of the receivers is such that there is no impairment in receiver sensitivity as a result of this 2-kc separation.

It is also necessary to control the phase of the modulation of the transmitters to prevent cancellation of the audio tones in the receiver. Practically, the author has found that if the difference in phase is held within 45 degrees, there is no decrease in receiver sensitivity when two radio signals of equal intensity are received.

Because of the more stringent frequency tolerances involved at 150 mc, it is doubtful whether similar techniques could be employed in this frequency band. The alternative is to maintain better frequency stability or to resort to sequential modulation of the base station transmitters: first sending the code from one and then repeating it slightly delayed in time from the other.

Service Range at Allentown

It is of interest to note the actual ranges obtained with the systems now in operation in Allentown and Columbus, Ohio. The bulk of the data was obtained using the pocket receivers themselves to indicate the service limits. The procedure was to have trained personnel carry the receivers in various areas a known distance from the land transmitters. The land station was arranged to signal these receivers repeatedly at a rate of two or three times per minute. The service reliability in a given area was then determined by comparing the number of calls received with the number actually transmitted during a 15- to 30-minute interval. The sensitivity of the receivers was checked at frequent intervals and a number of spot checks of field strength were made using conventional measuring equipment.

For reliabilities ranging from 90% to 100%, it was determined that the range of the Allentown system when used outdoors varied from 3 to 5 miles. This was obtained by the use of receivers which had a sensitivity in the order of 40 to 46 db above 1 microvolt per meter.

Experience concerning coverage within buildings is somewhat limited because most of the larger buildings in the Allentown area are located rather close to the transmitter sites. Based on a small sample, the range is fairly close to that which might be predicted, varying from 0.5 to 1.0 mile on the first floors of the buildings investigated.

Commercial service was initiated in Columbus on May 1, 1958. In this case the transmitting antenna location is well above surrounding buildings and this has resulted in extended coverage. The service range to customers in streets is in the order of 12 miles. Data on coverage in buildings are again limited because most of the larger buildings are grouped near the transmitter in the downtown district. Ranges in the order of 5 to 6 miles seem to be typical for the

Vol.
Pt. 1
1959

smaller industrial buildings in the suburbs.

When the pocket receivers are used in an automobile, the useful range depends largely on the exact placement of the unit. With the receiver in the driver's pocket, the useful service range in Columbus varies from 3.5 to 6 miles. If the receiver is fastened up near the sun visor, some improvement is obtained and ranges in the order of 7 to 10 miles seem to be typical.

Central Office Facilities

The earlier papers have described in some detail the type of central office equipment now being used in Allentown, Pa. This installation, by way of review, is a completely manual system. The calling party must contact an operator and provide the correct 4-digit code. This code is placed into the system by the operator who sets four rotary switches and operates a start switch. This information is then translated into the series of four audio tones which are used to modulate the radio transmitters. After the call has been transmitted three times (since other calls are interleaved this may take approximately 3 minutes), the operator removes the call from the system by throwing a switch to the off position. In this system the operator is required to prepare a ticket indicating the numbers of the parties involved and the time of day at which the call was placed.

In order to reduce the operator's work load, the system now in operation in Columbus has facilities to allow the operator to place calls into the system using a dial or keyset from a standard switchboard position. The digits are stored in a series of stepping relays. Two or more of these storage registers can be provided so that a number of calls can be placed into the system simultaneously. Since personal signaling service and mobile telephone service are being provided on the same radio frequency in Columbus, control equipment is provided to permit the two services to use the channel alternately. When the channel is available for signaling, the information in the registers is translated into the sequence of tones which are then directed to the radio transmitters. The information in the registers is automatically erased after the message has been transmitted the required number of times and a lamp then indicates to the operator that the register is available for the next call. As in the Allentown case, the operator must prepare a ticket to allow the call to be charged properly.

Future Development

With the solving of these receiver, transmission, and central office problems, another plateau has been reached and more work lies ahead.

The next logical step, and one that is now under consideration, is that of allowing the calling parties to dial calls directly into the signaling system. From a systems planning standpoint this involves arriving at an arrangement which can work with the many different types of telephone offices now in use. This includes step-by-step, panel, and various types of crossbar systems. Effort is also being directed toward the streamlining of the accounting procedure. Ideally, the goal is to make use of automatic message accounting techniques (AMA) to record the traffic data.

From a transmission standpoint, there is still much to be learned regarding the variations in field strength both in the bands now in use and at higher frequencies. A related problem, and a very important one, is the design of miniature antenna arrangements which can abstract the optimum amount of power from the complex radio field patterns which exist in urban areas.

Finally, there is the problem of devising still smaller receivers: receivers that have a high order of sensitivity, selectivity, and stability, and that are capable of high signaling speeds. These are the challenges before the research, planning, and development groups—technology of the future must be coupled with experience from the past to arrive at solutions which are both operationally and economically satisfactory.

Design of Random-Noise Transformers

M. P. VORE
MEMBER AIEE

Synopsis: This paper develops a method of choosing the core required for transformers which must handle random-noise voltages. Experimental verification of this method is briefly described. The early portion of the paper describes briefly some of the characteristics of random noise and outlines the method of calculating the random current produced in a complex impedance by a random voltage.

RANDOM-NOISE voltages and currents are coming into use in a variety of practical ways. This has caused the development of apparatus to generate, amplify, measure, and utilize random-noise power.

One very important recent field of application is in the testing of air-borne military components. The specifications for many of these require testing under conditions of random vibration. The power capability of the electric equipment which supplies random noise power to vibration shakers ranges up to 70 kva.

The design of random-noise power supplies requires a knowledge of the behavior of random voltages, currents, magnetic fluxes, and the relationships among them analogous to that which exists for sinusoidally varying quantities. The design of transformers carrying random-noise power is of particular interest because these components are usually specially designed for the application, have a relatively long delivery cycle, and represent an appreciable proportion of the total cost of the apparatus. All in all, the equipment designer just cannot afford to be wrong in his transformer design and application.

When this author was faced with the necessity of designing a transformer to

---

Paper 57-1015, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 7–11, 1957. Manuscript submitted July 1, 1957; made available for printing August 12, 1957.

M. P. Vore is with the Westinghouse Electric Corporation, Baltimore, Md.

handle high-power random noise, a search of the literature provided nothing that was directly applicable to the problem although the fundamental mathematical tools for solving it are well documented.[1,2] It is felt therefore that this paper describing the application of basic theory to the design of random noise transformers may be helpful.

It is helpful to begin by describing some of the basic calculations involved in handling random electrical quantities. Rigorous mathematical justification for the steps taken may be found by consulting the mathematical literature previously cited.

Elements of Random Noise

If a voltage is varying completely at random, neither its value nor its rate of change can be predicted for any given instant.

Similarly there are random-noise currents. The "shot effect" current in an electron tube is a classic example of a random-noise current. The noise voltage generated in a resistor by the random motion of the free electrons in it is an example of a random-noise voltage.

EXAMPLES OF RANDOM NOISE

On an oscilloscope random noise looks like the familiar "hash" or "grass." When applied to a transducer random noise sounds like the hiss of a sensitive radio receiver tuned between stations.

POWER SPECTRUM

A random-noise voltage may be thought of as composed of infinitely many sinusoidal components of all of the frequencies in the noise bandwidth. These components have random phases.

The power content of the voltage may be distributed uniformly or nonuniformly in the total bandwidth of the noise. This distribution with frequency of the noise voltage is known as its "power spectrum." The power spectrum of a random voltage or current forms the starting point for many calculations involving random quantities.

The power spectrum of a random voltage is the power per unit bandwidth that would be dissipated by a 1-ohm resistance to which the random voltage is applied. A similar definition applies to the power spectrum of a random current. In general these are functions of frequency.

In the following, the power spectra of random voltages and currents will be denoted by E_f^2 and I_f^2 respectively, and their rms values by E_r and I_r.

$$E_r^2=\int_0^\infty E_f^2 df \tag{1}$$

$$I_r^2=\int_0^\infty I_f^2 df \tag{2}$$

If the voltage or current has its power spectrum confined within the bandwidth f_1 to f_2 the limits of integration become f_1 to f_2.

Conceivably, the power spectrum of a random voltage could be determined experimentally by connecting a thermocouple voltmeter to a random-voltage source through a filter with a 1-cycle passband. Then, as this 1-cycle passband is scanned through the frequency range, the power spectrum is the average value of the square of each meter reading plotted against its corresponding midband frequency.

It will be apparent by this time that any quantity such as magnetic flux which varies at random has the characteristics of random noise. It is possible and convenient to define a power spectrum for them in an analogous manner.

WHITE NOISE

If a random voltage or current has a constant power spectrum over its bandwidth it is termed "white noise" by analogy to white light which has a uniform energy distribution.

RELATIONS BETWEEN RANDOM VOLTAGE AND CURRENT

When a random voltage having a power spectrum E_f^2 is applied to a frequency-dependent impedance Z, the power spectrum of the resulting current is

$$I_f^2=\frac{E_f^2}{|Z(f)|^2} \tag{3}$$

The rms current is found from

$$I_r^2=\int_0^\infty \frac{E_f^2}{|Z(f)|^2} df \tag{4}$$

For example, suppose a white noise voltage of rms value E_r with a bandwidth from f_1 to f_2 is applied to a series circuit of inductance L and resistance R. The power spectrum of the white noise voltage is

$$E_f^2=\frac{E_r^2}{f_2-f_1} \text{ for } f_1<f<f_2 \tag{5}$$

$$E_f^2=0 \qquad \begin{matrix} f<f_1 \\ f>f_2 \end{matrix} \tag{6}$$

Substituting equation 5 in equation 3, the power spectrum of the current is

$$I_f^2=\left(\frac{E_r^2}{f_2-f_1}\right)\left(\frac{1}{R^2+4\pi^2f^2L^2}\right) \tag{7}$$

It is interesting to note that due to the fact that the impedance is frequency-dependent, the current caused by a white noise voltage is not a white noise current. The mean square value of the current is

$$I_r^2=\int_{f_1}^{f_2} \frac{E_r^2}{f_2-f_1}\,\frac{1}{R^2+4\pi^2f^2L^2}\,df \tag{8}$$

In this case the limits of integration are from f_1 to f_2 only because the power spectrum of the voltage is zero outside of this frequency band.

Carrying out the indicated operations, the rms value of the current is as follows:

$$I_r=\frac{E_r}{\sqrt{2\pi LR}\,\sqrt{f_2-f_1}\Big/\sqrt{\tan^{-1}2\pi\frac{L}{R}f_2-\tan^{-1}2\pi\frac{L}{R}f_1}} \tag{9}$$

The expression in the denominator may be thought of as a "random noise impedance" Z_n.

The power dissipated in the resistor is

$$P=I_r^2R \tag{10}$$

PROBABILITY DENSITY

The probability that a random voltage at any instant has a value between v and $v+dv$ can be defined and written mathematically. It is

$$P=G(v)dv \tag{11}$$

$$P=\frac{1}{\sqrt{2\pi}v_r}e^{-\frac{1}{2}\frac{v}{v_r^2}}dv \tag{12}$$

where

v = the instantaneous voltage
v_r = the rms value of the voltage

The function

$$G(v)=\frac{1}{\sqrt{2\pi}v_r}e^{-\frac{1}{2}\frac{v^2}{v_r^2}} \tag{13}$$

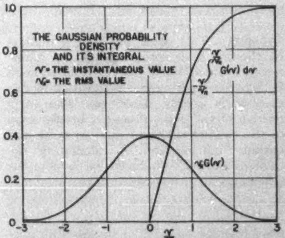

Fig. 1. Plot of the Gaussian probability density and its integral

is the Gaussian probability density function.

The probability that the random voltage is between two discreet values v_1 and v_2 is

$$\int_{v_1}^{v_2} G(v)dv \tag{14}$$

It may be shown that

$$\int_{-\infty}^{\infty} G(v)dv=1 \tag{15}$$

$G(v)$ is called the probability density.

Fig. 1 is a plot of $v_r G(v)$ and of the integral of $G(v)$ between the limits $-v/v_r$ and $+v/v_r$. This latter is the probability that the random voltage at any instant is numerically less than the abscissa times its rms value.

Values of the probability integral

$$\frac{2}{\sqrt{\pi}}\int_0^x e^{-x^2}\,dx$$

may be found tabulated to several decimal places.[3]

Random-noise currents, or magnetic fluxes, also have a Gaussian probability density. That is, for a random current

$$G(I)=\frac{1}{\sqrt{2\pi}I_r}e^{-\frac{1}{2}\frac{I^2}{I_r^2}} \tag{16}$$

or for a random flux

$$G(\phi)=\frac{1}{\sqrt{2\pi}\phi_r}e^{-\frac{1}{2}\frac{\phi^2}{\phi_r^2}} \tag{17}$$

It can be shown that the probability density function is not influenced by the power spectrum of the random quantity. In particular, for instance, a random voltage will produce a random current through an impedance or a random flux in a transformer core, and the resulting current or flux will have a Gaussian probability density.

PRACTICAL PEAK VALUE OF A RANDOM VOLTAGE OR CURRENT

In designing apparatus to handle random noise one must make an engineering decision concerning the maximum peak values of voltage or current or magnetic flux the apparatus will handle. The Gaussian probability density function indicates that there is a mathematical probability that the voltage may be of any size, even infinitely large. The probability that a random quantity will exceed three times its rms value is only 0.3%, however. Therefore, in designing apparatus containing vacuum tubes or transformers or the like having a limited linear operating range one designs so that the linear portion of the range will extend to three times the rms value of the random quantity to be handled.

Transformer Design

CORE FLUX

In designing a transformer for random voltages the designer is faced with the problem of choosing a core that will not saturate on the random voltage peaks of three times the rms value. He could proceed to design a transformer that would handle a sine wave voltage whose crest value is equal to the three times the rms value of the noise voltage at the lowest frequency in the noise bandwidth. Such a transformer would perform satisfactorily but it would be unnecessarily large and uneconomical as will be shown.

When a random voltage is applied to a transformer winding, a random flux is produced in the core. This flux has a Gaussian distribution, and its mean square value may be found by a method analogous to the one just used to find the mean square value of current through an impedance.

$$\phi_r^2=\int_{f_1}^{f_1}\frac{E_f^2}{4\pi^2n^2f^2}df\times 10^{16} \tag{18}$$

where n is the number of turns of the winding.

For instance, if a white noise voltage of rms value E_r and bandwidth from f_1 to f_2 is applied to a transformer winding of n turns, the mean square flux produced in the core is

$$\phi_r^2=\int_{f_1}^{f_2}\frac{E_r^2}{f_2-f_1}\frac{1}{4\pi^2n^2f^2}df\times 10^{16} \tag{19}$$

Working this out, the rms value of the random flux is

$$\phi_r=\frac{1}{2\pi n}\frac{E_r}{\sqrt{f_1f_2}}\times 10^8 \tag{20}$$

For comparison, note that the rms value of the sinusoidal flux produced by a sine wave voltage of rms value E_{rs} and frequency f_s is

$$\phi_{rs}=\frac{1}{2\pi n}\frac{E_{rs}}{f_s}\times 10^8 \tag{21}$$

If one were designing a transformer for a sinusoidal voltage he would pick a crest value of flux ϕ_{ms} (usually limited by saturation) at which he wishes the core to operate.

$$\phi_{ms}=\sqrt{2}\,\phi_{rs} \tag{22}$$

It is convenient to work with flux linkages rather than flux and so the following is written:

$$n\phi_{ms}\times 10^{-8}=\frac{\sqrt{2}}{2\pi}\frac{E_s}{f_s} \tag{23}$$

EQUIVALENT SINUSOIDAL VOLTAGE

White Noise

In the random-noise case the peak value of flux for which one designs is three times the rms value and one designs the transformer so that this is numerically equal to the value considered allowable for the sinusoidal case, i.e.,

$$\phi_{ms}=3\phi_r \tag{24}$$

Thus, the following equivalences result:

$$n\phi_{ms}\times 10^{-8}=\frac{\sqrt{2}}{2\pi}\frac{E_s}{f_s} \tag{25}$$

for the sinusoidal case, and

$$n\phi_{ms}\times 10^{-8}=\frac{3}{2\pi}\frac{E_r}{\sqrt{f_1f_2}} \tag{26}$$

for the white noise case. From these

$$\frac{E_s}{f_s}=\frac{3}{\sqrt{2}}\frac{E_r}{\sqrt{f_1f_2}} \tag{27}$$

Therefore, in practice, to choose a core size for a transformer to handle a random-noise voltage of rms value E_r and bandwidth f_1 to f_2, one defines an equivalent sinusoidal voltage E_s and frequency f_s as in the foregoing and chooses a core size that would be satisfactory for that.

It can be seen that this analysis allows the use of a considerably smaller core than would have been chosen on the basis of capability to handle a sinusoidal voltage of crest value equal to the peak value of the noise voltage and of frequency equal to the lowest frequency in the noise bandwidth as follows.

Core size is proportional to the flux linkages it handles provided the turns remain constant. Hence if instead of choosing a core size proportional to

$$n\phi_{ms}\times 10^{-8}=\frac{3}{2\pi}\frac{E_r}{\sqrt{f_1f_2}} \tag{28}$$

it had been chosen proportional to

$$n\phi'_{ms}\times 10^{-8}=\frac{3}{2\pi}\frac{E_r}{f_1} \tag{29}$$

the core would have been unnecessarily large by a factor of $\sqrt{f_2/f_1}$. Evaluating this for a bandwidth even as narrow as 30 to 300 cycles, the ratio is $\sqrt{10}=3.16$, which is considerable.

The reason for this is that the flux in the core is proportional to the area under a positive or negative voltage loop. The probability that such a loop will have a crest value equal to three times the rms value and simultaneously have a width corresponding to the lowest frequency in the noise bandwidth is considerably less than the probability that the voltage will simply reach a crest value of three times rms.

Shaped-Noise Spectrum

A slightly more complicated case that has been worked out is the calculation of flux caused by a white noise voltage of bandwidth f_1 to f_2 that was first put through a network having a frequency response decreasing at the rate of 6 decibels per octave with increasing frequency.

In this case the frequency spectrum of the voltage is

$$\frac{E}{E_0}=\frac{1}{f} \tag{30}$$

where E_0 = a constant.

Its mean square value E_r^2 and power spectrum E_f^2 are related as follows:

$$E_r^2=\frac{1}{f_2-f_1}\int_{f_1}^{f_2}\frac{E_0^2}{f^2}\,df=\int_{f_1}^{f_2}E_f^2df \tag{31}$$

From this it can be seen that the power spectrum of the voltage is

$$E_f^2=\frac{1}{f_2-f_1}\;\frac{E_0^2}{f^2} \tag{32}$$

One now evaluates E_0 in terms of the observable rms value E_r as follows:

$$E_r^2=\int_{f_1}^{f_2}E_f^2df \tag{33}$$

$$E_r^2=\int_{f_1}^{f_2}\frac{1}{f_2-f_1}\;\frac{E_0^2}{f^2}\,df \tag{34}$$

$$E_r^2=\frac{E_0^2}{f_2f_1} \tag{35}$$

Substituting the value of E_0^2 in the expression for E_f^2 (equation 32) gives

$$E_f^2=\frac{f_2f_1}{f_2-f_1}\;\frac{E_r^2}{f^2} \tag{36}$$

which is more practical to work with because one can observe E_r with an rms reading meter.

Now it is possible to compute the mean square core flux by the method used earlier.

$$\phi_r^2=\int_{f_1}^{f_2}\frac{E_f^2}{4\pi^2f^2n^2}\,df\times 10^{16} \tag{37}$$

$$\phi_r^2=\int_{f_1}^{f_2}\frac{f_1f_2}{f_2-f_1}\;\frac{E_r^2}{4\pi^2n^2}\;\frac{df}{f^4}\times 10^{-16} \tag{38}$$

Working this out gives

$$10^{-8}n\phi_r=\frac{1}{2\pi\sqrt{3}}\;\frac{E_r}{\sqrt{f_1f_2}}\sqrt{\frac{f_2}{f_1}+1+\frac{f_1}{f_2}} \tag{39}$$

For comparison note the expression for rms flux linkages for the white noise case

$$10^{-8}n\phi_r=\frac{1}{2\pi}\;\frac{E_r}{\sqrt{f_1f_2}} \tag{40}$$

and it is seen that in all cases the flux caused by this shaped-voltage distribution is greater than it is for the white noise case. This is as it should be because in this latter case the voltage spectrum is weighted toward the low-frequency end.

By proceeding as before, it is possible to find an equivalent sine wave voltage and frequency that will produce a crest value of flux linkages equal to three times the rms value of noise flux linkages. This is used as the basis of choice of core size.

Utilizing previous work,

$$\begin{aligned} n\phi_{ms}\times 10^{-8}&=\frac{\sqrt{2}}{2\pi}\;\frac{E_s}{f_s}\\ &=\frac{3}{2\pi\sqrt{3}}\;\frac{E_r}{\sqrt{f_1f_2}}\sqrt{\frac{f_2}{f_1}+1+\frac{f_1}{f_2}} \end{aligned} \tag{41}$$

This simplifies to

$$\frac{E_s}{f_s}=\frac{3}{\sqrt{6}}\;\frac{E_r}{\sqrt{f_1f_2}}\sqrt{\frac{f_2}{f_1}+1+\frac{f_1}{f_2}} \tag{42}$$

Experimental Verification

The validity of this method has been experimentally verified in both the case of white noise and noise with a sloping power spectrum. The method used was to establish for an existing transformer the value of 60-cycle sine wave voltage at which the core entered saturation. This was done by observation of magnetizing current. Next, by observation of magnetizing current the value of noise voltage at which the core entered saturation was observed. The results were in good agreement with equations 27 and 42 respectively. It was quite easy to tell when saturation occurred in the random-noise case because occasional peaks would cause violent deflections of the magnetizing current ammeter when the rms noise voltage was too great.

TURNS RATIO

So far only the problem of choice of core size in random noise transformers has been dealt with. Turns ratio, of course, is the ratio of rms voltages just as in the sinusoidal case.

COPPER AND CORE LOSSES

Copper loss in each winding is calculated simply from the square of the rms random current times winding resistance as in the sinusoidal case.

Core-loss data for random fluxes do not exist. From the fact that the random flux reaches a peak value far less often than it does when the equivalent sine wave voltage and frequency (equations 27 or 42) are applied, one would expect core loss for the random case to be less than it is for the equivalent sinusoidal case. This was also verified experimentally by measuring the rate of core temperature rise of two identical transformers, one operated open circuit at its random noise rating and one at its equivalent sine wave rating. The sine wave transformer had a measurable and reasonable core temperature rise. The random-noise transformer, however, developed no perceptible rise in core temperature.

OTHER TRANSFORMER CONSTANTS

Depending upon how faithfully the power spectrum of the input voltage must be reproduced, and upon allowable phase shifts if the transformer is to be included in a feedback loop, the effects of magnetizing current, leakage inductances, and winding capacitances may be analyzed by the methods used for sine wave transformers operating over the frequency band of interest.

Possible Extensions

Preceding portions of this paper have outlined a basic method of computing the rms value of random flux in a transformer core, and have worked out two examples for rather simple random-noise voltage power spectra. This method can be extended to more complicated noise voltage power spectra. In doing this one may plot the integrand of equation 18 on a linear scale and integrate graphically to find the mean square value of random flux.

Alternatively, one might plot the voltage power spectrum in decibels on a logarithmic frequency scale, then approximate this curve by straight lines having slopes that are multiples of 12 decibels per octave. One could then set up integrals between the corner frequencies in a manner analogous to the steps taken from equations 30 to 42 and carry out the integrations analytically. The result would be an approximation that probably would be sufficient for practical purposes.

The general philosophy of this analysis might conceivably be profitably extended transformers for communication, speech, and music which are, in a sense, random signals. Some investigation would be necessary, however, to determine an appropriate power spectrum of the signal voltage and an appropriate probability density which will guide a decision as to maximum crest values of signal to be accommodated.

Properties of Octafluorocyclobutane, a Dielectric Gas

F. W. BLODGETT
NONMEMBER AIEE

THERE IS a continuing need for improvement in all types of electric equipment. New applications call for higher operating temperatures, better reliability, smaller size, lighter weight, and little, if any, increase in cost. At the present level of design perfection, new materials having better properties are often required for making equipment which can handle higher voltages, or more power per pound or per cubic foot.

This paper describes the properties of a new dielectric gas. Enough data have already been obtained to show that octafluorocyclobutane, or C_4F_8, has a combination of properties making it very interesting for use in new electric equipment.

Electrical Properties

Octafluorocyclobutane, which is also called perfluorocyclobutane, is a cyclic fluorocarbon. Like other fluorocarbons, it is very stable, even at elevated temperatures. Also like other volatile fluorocarbons, C_4F_8 is an electronegative gas, i.e., it has a strong affinity for electrons. Its combination of electronegativity, high molecular weight, and chemical stability is responsible for its outstanding electrical properties.

In an electric field, C_4F_8 absorbs electrons to form ions of low mobility. This results in a fairly stable space charge which tends to make the electric field more uniform, and it greatly reduces the tendency of the electrons to form a conductive path. As a result, C_4F_8 has a high dielectric strength or breakdown voltage.

Breakdown voltage. Fig. 1(A) shows the breakdown voltage of C_4F_8 in a fairly uniform electric field. For easy reference, C_4F_8 is compared with air and with sulfur hexafluoride (SF_6), another electronegative gas which has already been used in some high-voltage electric equipment. As Fig. 1(A) shows, C_4F_8 has about the same dielectric strength as SF_6 at very close electrode spacing where the electric field is very nearly uniform. At wider spacings, where the field becomes less uniform, C_4F_8 will sustain 20% to 30% higher voltages than SF_6.

Nonuniform fields. The breakdown voltages of these gases are slightly less in a nonuniform than in a uniform field. Fig. 1(B) shows the higher dielectric strength of C_4F_8 as compared to SF_6. Although both electronegative gases are far superior to air, C_4F_8 sustains 30% to 50% higher voltages than SF_6.

Electrode geometry. The electrodes used to study dielectric strength in uniform electric fields were two chromium-plated disks, 3 inches in diameter, with suitably rounded edges. The set used for nonuniform fields was a 1/4-inch square aluminum rod and a 3-inch grounded disk. In both sets, electrode spacing was adjusted by means of a micrometer connected to one of the electrodes. The two sets of electrodes were used in a cylinder, with an 8-inch inside diameter, made of transparent plastic and filled with the gas to be tested.

Corona. There are no data for corona-starting voltages for C_4F_8, but an indication of the high voltages required for corona is given in Fig. 2, which compares the corona voltages for $n\text{-}C_4F_{10}$ with those for air in a nonuniform electric field. The gas $n\text{-}C_4F_{10}$ is the straight-chain fluorocarbon comparable to cyclic C_4F_8, and the electrical properties of these two fluorocarbon gases are very similar.

Paper 58-326, recommended by the AIEE Electrical Insulation Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, N. Y., June 22–27, 1958. Manuscript submitted March 13, 1958; made available for printing August 14, 1958.

F. W. Blodgett is with E. I. du Pont de Nemours and Company, Inc., Wilmington, Del.

The electrical data on C_4F_8 and the other gases shown in the figures of this paper were determined by Camilli, et al.,[1] and the authors take this opportunity to acknowledge their indebtedness to them.

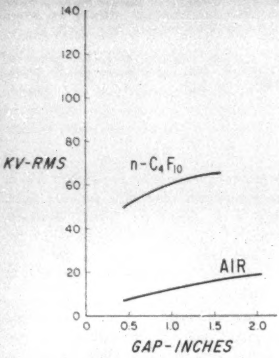

Fig. 2. **Corona voltage, nonuniform field**

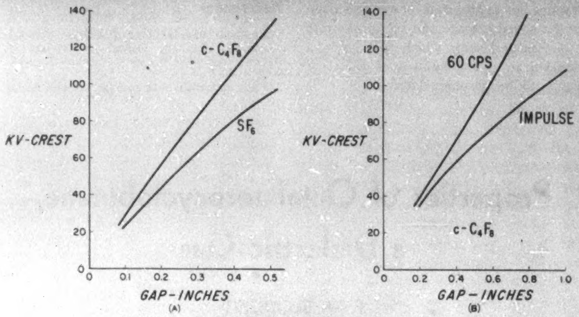

Fig. 3. **Impulse breakdown voltage**

A—Uniform field
B—Nonuniform field

C_4F_8 may be expected to have corona voltages 4 to 6 times higher than air, with the higher ratios in the more nonuniform fields. As yet the author has no data on the formation of any chemical breakdown products that may be formed from C_4F_8 during continuous corona operation.

Impulse. The behavior of dielectric gases under impulse voltages is important if the gas is to be used in equipment that can be subjected to impulses caused by switching in reactive circuits or by lightning.

Fig. 3(A) shows the breakdown voltages of C_4F_8 and SF_6, with the standard 1.5x40-microsecond positive impulse. In a uniform field, C_4F_8 has a higher impulse breakdown voltage than the 60-cycle breakdown voltages shown in Fig. 1(A), even when these are converted to crest voltages. C_4F_8 maintains its breakdown voltage difference, as compared to SF_6.

In contrast to the higher impulse breakdown voltage in a uniform field, electronegative gases have an impulse breakdown voltage lower than the 60-cycle breakdown voltage in a nonuniform field. Fig. 3(B) shows this difference for C_4F_8 in a nonuniform field, with the 1.5x40-microsecond positive impulse.

The negative impulse breakdown voltages in a nonuniform field for a series of fluorocarbon gases have been found to be considerably higher than the positive impulse breakdown voltages,[2] so that it is expected that the positive impulse breakdown voltages will be the critical values for application to electric apparatus design.

Pressure. The dielectric strength of all gases in a uniform electric field increases linearly with pressure, although the slopes and intercepts of different gases are different. These differences depend on the molecular structures of the gases in a way which is not yet understood.

Fig. 4(A) shows the breakdown voltages of C_4F_8, SF_6 and air at pressures up to 25 psig (pounds per square inch gage). The data for C_4F_8 were estimated from its breakdown voltage at atmospheric pressure and the slope of the breakdown voltage for its linear homolog, *n*-C_4F_{10}.

In a nonuniform field, on the other hand, corona and space charge effects distort the linear relationship. Fig. 5 shows that both the 60-cycle and the positive impulse breakdown voltages of C_4F_8 go through a maximum at relatively low pressures and that the impulse curve is almost flat. The author does not have data on SF_6 with the same set of electrodes. Therefore, if the field is nonuniform, there is no advantage in using an electronegative gas at a high pressure. As a matter of fact, in a closed system, careful control of the gas pressure by controlling temperature would be necessary to obtain reliable performance at the maximum dielectric strength rating.

Gas mixtures. Recent work at the General Electric Company[1,3] and the Westinghouse Electric Corporation[2,4] has shown how this anomalous behavior of electronegative gases can be controlled so that the high dielectric strengths of electronegative gases at high pressure can be used even in nonuniform electric fields. The ability of these electronegative gases to capture electrons and prevent break-

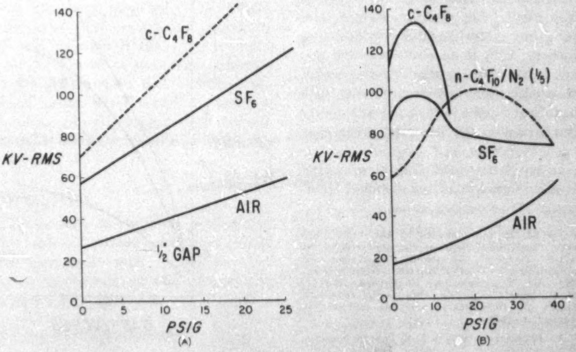

Fig. 4. **Breakdown voltage under pressure**

A—Uniform field
B—Nonuniform field, 1-inch gap

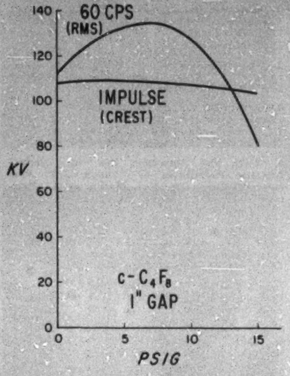

Fig. 5. Positive impulse breakdown voltage under pressure, nonuniform field

down is so great that they have a strong effect even when diluted with nitrogen. The nitrogen increases the pressure range over which the mixture shows increasing dielectric strength with increasing pressure. This effect is shown in Fig. 4(B) with n-C_4F_{10}.

In a nonuniform field, the dielectric strengths of C_4F_8 and SF_6 reach maximum values at rather low pressures. But a mixture of n-C_4F_{10} and nitrogen, at a ratio of one part n-C_4F_{10} to five parts of nitrogen by volume, reaches a high dielectric strength at moderate pressures and has a somewhat broader maximum, so that accurate pressure control is not so critical as with the pure gas. Although a patent claiming this same effect with C_4F_8 has been issued,[3] no data obtained with this particular set of electrodes have been published.

100	38	52.1
150	66	125.3

Depending on the operating temperature range and the uniformity of the electric field, these mixtures of electronegative gases with nitrogen may show a cost advantage over the pure gas at comparable dielectric strengths. The mixtures also permit operation of a dry gas system at higher pressures and lower temperatures than does the pure electronegative gas, because the partial pressure of the condensable gas remains relatively low.

Physical Properties

C_4F_8 is a dense, colorless, odorless gas at atmospheric temperature and pressure. Its molecular weight, boiling and freezing points, and critical data are shown in Table I.[5]

Since C_4F_8 has a fairly high boiling point its vapor pressure is moderate at room temperature. Table II shows the vapor pressure,[5,6] over a range of temperatures. Although this limits the temperature range at which pure C_4F_8 may be used in dry dielectric gas-filled apparatus, it makes it practical for evaporative cooling applications. Its chemical inertness and its very low solvent power for magnet wire insulation and other solid insulation means that liquid C_4F_8 can be sprayed onto transformer coils in a closed system where it will remove heat by evaporation, and then condense on the shell, giving up the heat to the atmosphere. C_4F_8 has a heat of vaporization of 49.8 Btu/lb (pound) or 28 cal/g (calories/gram) at its normal boiling point.

Gas mixtures. When one volume of C_4F_8 is diluted with four volumes of nitrogen, the mixture can be used as a dry gas down to temperatures of −12 C (10 F) at 40 psig, or down to −38 C (−36 F) at atmospheric pressure. Further data are shown in Table III.

Density. The densities of the saturated vapor and of the liquid at various temperatures are shown in Table IV.[5]

Viscosity. The viscosity of liquid C_4F_8 at 70 F is 0.455 centipoise and the viscosity of C_4F_8 vapor at 70 F and 1 atmosphere pressure is 0.0117 centipoise.[7]

Surface tension. The surface tension of liquid C_4F_8 at 68 F is 8.41 dynes/centimeter.[8]

Solvent power. Both liquid and gaseous C_4F_8 have very low solvent powers for oils, rubber compounds, and magnet wire enamels. Its solubility in refrigeration oil is about 15% by weight at 68 F, and the solubility of oil in liquid C_4F_8 is about 2% by weight at 68 F. So little C_4F_8 dissolves in rubber that it does not leak from a rubber balloon. After immersion in liquid C_4F_8, the tensile strength of a neoprene compound was 85% of its original value.[7]

Structure and polarization. The detailed structure of C_4F_8 has been established by electron diffraction[9] and infrared absorption.[10] As would be expected from its symmetry as a ring compound, C_4F_8 has a zero dipole moment.[11] This means that its electrical loss factor is very low. Because of the high electronegativity of fluorine, the molar refraction of C_4F_8 is 19.2, the molar polarization is 24.8, the electronic polarization is about 18.5, and the atomic polarization is 6.3.[11]

Thermodynamic properties. Data for the thermodynamic properties of C_4F_8 have been obtained,[5] and values of the important functions are available.

Chemical Properties

C_4F_8 is a saturated cyclic fluorocarbon having four CF_2 groups connected in a ring. Like other saturated fluorocarbons, it is very stable chemically. Like other electronegative gases containing halogen atoms, C_4F_8 is ionized by high-energy electrons, losing a fluorocarbon ion, rather than an electron, to form a heavy positive ion. The low mobilities of these ions in an electric field are important factors contributing to its high dielectric strength. Its ionization potential is about 12.8 electron volts.[7]

Chemical reactions. C_4F_8 is highly stable, having a heat of formation of 352 kcal/mole.[12] It does not react with other materials under ordinary chemical conditions. At high temperatures, it dissociates to form carbon tetrafluoride and carbon.[7] The rate of this reaction has not been measured accurately, but it becomes rapid only above 600 C unless catalysts are present. Other products of high-temperature dissociation of C_4F_8 include toxic unsaturated fluorocarbons, such as tetrafluoroethylene[7] and octafluoroisobutylene.[13] Nickel and Inconel are inert, so C_4F_8 may be used continuously with these metals at temperatures up to 400 C. Steel, bronze, and yellow brass catalyze the decomposition and should not be used at temperatures above about 250 C. Steel and copper test pieces sealed in glass tubes with refrigeration oil and C_4F_8 caused no decomposition and showed no copper plating or corrosion during 500 days at 150 C. Copper with C_4F_8 alone does not tarnish at 232 C. C_4F_8 stability tests are still in progress.

Flammability. C_4F_8 was tested in a combustion buret. It is nonflammable in all proportions in air, but some mixtures with pure oxygen can be ignited by a spark. The products are carbon tetrafluoride, carbon dioxide and carbonyl fluoride.[7] This behavior is similar to that of other fluorogases.

When 10 pounds of C_4F_8 was mixed with the air in a 1,000-cu-ft (cubic-foot) test room, and a 2-burner gas stove was started, analysis of the well-mixed air showed 1.08% carbon dioxide, 0.038% carbon monoxide, 0.79% hydrogen fluoride, and 0.016% carbonyl fluoride after 30 minutes' burning time. This indicates the hazard of breathing mixtures of C_4F_8 and air that have been exposed to arcs or flames. Since hydrogen fluoride is very irritating in small concentrations, there is ample warning of the hazard.

Hydrolysis. C_4F_8 is extremely stable to hydrolysis. Neutral, alkaline, and acidic aqueous solutions saturated with C_4F_8 at temperatures up to 130 F (54 C) in lacquer-lined tin-plated steel cans for one year showed less than one part per million fluoride ion concentration in the aqueous phase.[7]

Toxicity

Preliminary work shows that the toxicity of C_4F_8 is very low, but adequate ventilation should be used in any experimental work until the results of further toxicity tests, which are now in progress, are available. Breathing C_4F_8 that has been exposed to flame temperatures should always be avoided, since under some conditions it may decompose slightly and contain toxic or irritating decomposition products. Samples of C_4F_8 or Freon-C318,[*] are now available for evaluation as a dielectric gas.

Magnet Wire for 600 C Temperature Transformers

W. W. WAREHAM
NONMEMBER AIEE

AS A PART OF WORK performed on a government contract, magnet-wire materials were investigated for application in electronic power transformers and inductors. One of the most critical environments specified for the application was 1,000-hour life in the ambient temperature range −65 C (degrees centigrade) to 500 C. This paper summarizes the planning and results of an ultrahigh-temperature heat-aging program designed to screen selectively the most promising magnet wires to meet this requirement.

Planning the Heat-Aging Program

An ambient temperature requirement of 500 C meant that the magnet wire would be exposed to even higher temperatures due to internal heat rise and hot-spot conditions. The actual requirement in terms of magnet-wire performance was therefore arbitrarily selected as 1,000 hours at 600 C. The selection of materials to be evaluated, the properties to be measured, and the type of test fixture to use were challenging questions which had to be answered before the program could be started.

SELECTION OF MAGNET WIRES

A survey of available magnet wires which had potentiality for performing 1,000 hours at 600 C revealed that the choices were quite limited. It was obvious that copper could not be used directly at this temperature, so the selection of the magnet wires involved both

the insulation and conductor materials. Much interest was focused on the possibility of using a ceramic-coated conductor but most of these materials were still in the development stage and available only in limited quantities. The major concern was to find a magnet wire that could be supplied in quantity by well-known manufacturing processes. Many insulations were considered but were rejected because of insufficient physical properties for winding, and some possessed inferior electrical properties at 600 C. The three samples which were selected for complete evaluation were:

1. A 0.0126-inch double glass-served silicone-varnish-treated, 27% nickel-clad copper wire.

2. A 0.0126-inch double glass-served silicone-varnish-treated silver wire.

3. A developmental sample of 0.0285-inch anodized aluminum wire. Although this wire is not available commercially, its excellent high-temperature properties, low film build, and long-range economic aspects made it a desirable candidate.

PROPERTIES TO BE MEASURED

Magnet-wire properties are usually investigated in terms of physical strength first and electrical and chemical properties later. This is true because magnet wire must be wound into a coil shape before it ever begins to perform its electrical function. Physical properties and nondestructive electrical properties were emphasized in the initial tests at room temperature.

Initial Tests at Room Temperature

Magnet-wire samples were tested for the following characteristics:

1. Flexibility per-cent elongation to crack insulation.

2. Step mandrel dielectric strength.

3. General Electric Repeated Scrape Abrasion Test.

4. Film build and concentricity of insulation.

5. Insulation resistance using a 35-volt d-c megohmmeter.

6. Twist dielectric strength.

7. Tensile strength, conductivity, and per-cent elongation of conductors.

Tests at Elevated Temperatures

A conditioning period of 40 hours at temperatures of 300 C, 400 C, 500 C, and 600 C was established to remove the volatile components of the wire insulation. New samples were used at each test temperature. Values of insulation resistance and dielectric strength were determined after each of the conditioning periods. These same readings were taken on another set of wires aged for 1,000 hours at 600 C. The tensile, elongation, and conductivity characteristics of the con-

ductors were also followed at these test conditions.

Type of Electrical Measurement Sample Fixture

A sample fixture had to be developed which was representative of transformer coil construction and would provide adequate support for the wire and allow readings to be taken at 600 C. The sample had to be simple and easily replicated. A tight single strand coil was wound around a 1/2-inch-diameter mandrel for a distance of 1 inch. Both ends of the coil were secured to the cylindrical mandrel by threading through ceramic bushings mounted in sets of two which were staggered 90 degrees alternately along the mandrel. Five such coils were mounted on a single 18-inch-long 304 stainless steel rod 1/2 inch in diameter which had been given a coat of flash nickel and then rhodium plated to protect against surface oxidation. The five coils were wound close together covering a distance of 10 inches along the rod. The next 2 inches of the rod were left open to provide space between a high-temperature oven door and the nearest coil. The remaining 6 inches of the rod protruded out through the door to be used for mechanical support and electrical connections. The leads from each of the five coils inside the oven were guided through the door and test rack by long ceramic tubes. Five coils wound on a single rod can be seen in Fig. 1(B).

Electrical measurements were taken between each of the five coils and the stainless steel mandrel. Two rods containing samples of each test wire were made for every temperature condition so that an average of ten readings could be obtained.

Discussion of Results

A comparison of the physical properties of the test specimens can be found in Table I. All the samples are deficient in insulation flexibility and abrasion resistance. However, all the wires could probably be used in transformer construction with proper care in handling.

Fig. 2 summarizes the initial step mandrel dielectric strength values as a function of mandrel diameter. The glass-served wire samples give by far the most protection even in the 0.125-inch mandrel. The anodized aluminum was lower but in terms of film build (volts per mil) it ranked the highest.

Figs. 3 and 4 show how heat exposure will change the tensile strength and percent elongation qualities of the three conductors. The wires illustrated an annealed effect with lower tensile and increased elongation.

Fig. 5 records the dielectric strength readings of the three wire samples which had been wound around the 1/2-inch-diameter rods and exposed to 300 C, 400 C, 500 C, and 600 C. The glass-served wires dropped from approximately 1,000 volts at room temperature to 600 volts at the four high-temperature levels. After 1,000 hours at 600 C the glass-served wires were still showing about 450 volts. The anodized aluminum wire remained quite constant at about 250 volts for all temperatues and improved to 300 volts after 1,000 hours at 600 C.

Some unusual insulation-resistance properties were observed from the data summarized in Fig. 6. The glass-served wires dropped from 250,000 megohms insulation resistance at room temperature to just a few megohms at 600 C. The glass-over-silver wire turned pale yellow after 1,000 hours at 600 C and an increase in insulation resistance was noted. The porous nature of the anodized aluminum wire and its ability to hold moisture

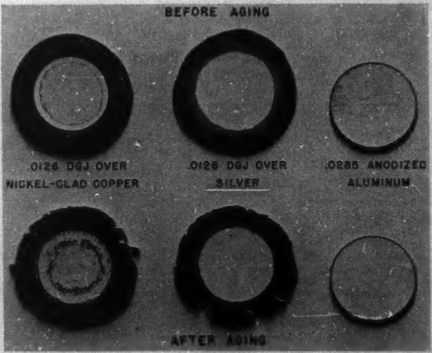

Fig. 8. Magnet wire cross sections before and after 1,000 hours at 600 C

(B)

(C)

Fig. 9. Wires aged 1,000 hours at 600 C

A—0.0285-inch anodized aluminum
B—0.0126-inch double, glass-served silver
C—0.0126-inch double, glass-served nickel-clad copper

caused rather low and erratic readings in the "as received" condition. However, added heating and drying improved the insulation resistance and it remained the highest of all samples tested. The 1,000-hour exposure at 600 C improved the insulation resistance over the 40-hour readings.

Fig. 7 shows the resistance values for the various conductors wound on a 1/2-inch-diameter mandrel for the following conditions:

1. Initial readings at room temperature.
2. Readings after 1,000 hours at 600 C taken at 600 C.
3. Readings after 1,000 hours at 600 C taken at room temperature.

All the conductors showed an increase in resistance at the end of 1,000 hours at 600 C except anodized aluminum. The nickel-clad conductor showed a serious increase in resistance. An explanation for this increase can be seen in Fig. 8, where the nickel has migrated into the copper forming a high-resistance alloy layer.

DESCRIPTION OF SAMPLES AFTER AGING

Fig. 9(A) shows the physical appearance of the anodized aluminum after 1,000 hours at 600 C. Small corrosion spots can be seen along the surface of the wire. The exact cause of these spots is unknown but it seems reasonable to assume that they may have been caused by remnants of corrosive electrolyte from the anodizing process. If this is the cause then it is important for all anodized wire to be thoroughly washed and cleaned before it is subjected to long exposures at high temperature.

Figs. 9(B) and 9(C) show how well the glass-served wire remained in good condition after 1,000 hours at 600 C. The glass fibers were extremely dry and brittle and could be scraped off easily but they remained in place to provide a consistent space factor.

All the photographs show a decided darkening of the rhodium plating which was used to coat the *304* stainless steel rods. In spite of the oxidation resistance and inertness of rhodium the severity of the test temperature and time did create an insulating film over the electrode. In order to determine the magnitude of this oxide coating, the layers of wire were carefully removed from the rods and replaced turn-by-turn with 0.010 bare copper wire. The insulation resistance between this wire and the rod averaged 0.6 ohm which indicated a very small barrier. As a second test a 1/4-inch strip of aluminum foil was wrapped around the rod at the end where no wire coil had been wound. The insulation resistance measured approximately 100,000 ohms at room temperature showing that the oxide film was much heavier where there had been no wire to protect the rod. This experience suggests that a platinum-clad electrode would be necessary to eliminate completely the interference of electrode oxide for conditions near 1,000 hours at 600 C or higher. Fig. 8 shows a composite of all the magnet-wire cross sections before and after the 1,000-hour exposure to 600 C. The nickel-clad copper formed a high-resistance alloy layer at the nickel-copper interface. Once the silicone varnish has been burned out of the glass-serving, the glass becomes loose and fragile as shown in the lower cross sections. Little change can be seen in the silver and aluminum conductors.

Conclusions

The results of this study have led to the following conclusions:

1. The 0.0126-inch double glass-served silicone-varnish-treated silver wire performed the best in most of the evaluation tests.

2. The 0.0126-inch double glass-served silicone-varnish-treated nickel-clad copper performed well except for the increase in conductor resistance brought about by a nickel-copper interaction after 1,000 hours at 600 C.

3. Anodized aluminum showed promise in most of the tests, especially when hot. This would be the recommended wire if low film builds become a necessity.

On the Anomaly in Residual Polarization of $BaTiO_3$ Ceramics

Y. SAITO
MEMBER AIEE

S. YAMANAKA
NONMEMBER AIEE

SPONTANEOUS polarization of barium-titanate ($BaTiO_3$) ceramics has been noted in research for its ferroelectricity and for its practical use. It is natural that a great deal of interest has been attached to spontaneous polarization as the property is quite essential in the ferroelectric phenomena. Nevertheless when measurements of residual polarization of $BaTiO_3$ were being made, the authors found that a very large amount of polarization occurred at times and it could not be attributed to spontaneous polarization in any case.[1] Blood and his co-workers[2] also found large residual polarization more than 150 μcoul/cm^2 (microcoulomb/centimeter^2) in $BaTiO_3$ ceramics accompanied by the anomalous phenomena in piezoelectric oscillation. After examining the phenomena it was recognized that some sort of polarization should be superposed upon the proper spontaneous polarization. As such phenomena are never favorable to the practical use of ferroelectric substance, investigations have been made especially to find a way to diminish their effect. Thus it was found that the mixing ratio of raw materials of the ceramics seemed to have a remarkable relation to the anomalous polarization, and the reduction of $BaTiO_3$ seemed to exist in accompaniment with such phenomena. The result obtained is reported in this paper.

Measurement of Residual Polarization and Samples Prepared for Measurement

Residual polarization of a ferroelectric dielectric which occurs below the Curie point will vanish if heated above that point. Making use of this property measurement of the total polarization of the dielectric is possible. Small plates of $BaTiO_3$ ceramics are used as specimens; they are glazed with silver and then soldered to terminal wires. Thus small plate condensers are formed. These are first heated above the Curie point to erase their history, then the condensers are polarized under various conditions. A polarized condenser is short-circuited for a moment at its terminals and then the terminals are connected to a ballistic galvanometer. Instantly it is immersed in a paraffin oil which has been heated beforehand at 170 C (degrees centigrade). Then the electric charge passing through the galvanometer, which is identical with the residual polarization of the specimen, is observed. However, the amount thus obtained contains some sorts of polarization and has comparatively large relaxation time in addition to the proper spontaneous polarization. For the purpose of abbreviation the symbols P_r, P_s, and P_t are used for total polarization, spontaneous polarization, and the difference between them respectively. We may sometimes call P_t anomalous polarization.

The samples employed have chemical composition, dielectric property, specific resistance, and other properties as shown in Table I. Such samples are sintered by duplicate heating. In the first stage, ingredients are mixed for 10 hours in a pot mill and then cakes are made from the mixture by pressing. These cakes are baked at 1,200 C for an hour. In the second stage the cakes are crushed in a pot mill again, then formed by pressing,

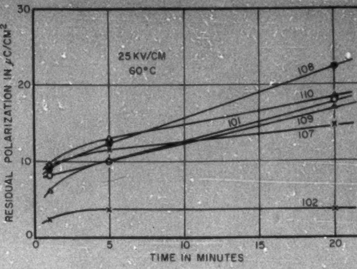

Fig. 2. Relation between residual polarization and time-of-voltage impression in $BaTiO_3$ ceramics prepared by various processes

and finally sintered at 1,400 C for an hour.

Dielectric properties are measured by the bridge method using high-frequency electric source of 1 kc. Specific resistance is measured by galvanometer deflection applying a direct potential of 100 volts on each specimen. As to the anomalous polarization P_i, shown in Table I, an explanation will be given later on.

Each specimen is a disk 10 mm (millimeter) in diameter and 0.5–1 mm in thickness. They are first silvered and then lead wires are soldered on both surfaces of the disks.

Factors Affecting Anomalous Polarization

Before examining a large number of measured samples, the relation between the residual charge P_r and the time-of-voltage impression t is precisely examined with a few samples. Comparatively high voltage is applied on each sample for 10 seconds, 1, 5, 10, 15, and 20 minutes successively. Examples of the relation between P_r and t are shown in Fig. 1. It is clear that the relations show straight lines on the major part of the curve except near its origin. Accordingly a few examples will be given for the purpose of determining the position of such a straight line since so many samples must be treated. Each characteristic illustrated hereafter is a typical result selected from the measurements on 5–10 samples.

The relation between P_r and t is measured with samples shown in Table I. Each measurement is always carried out at 60 C impressing 25 kv/cm. Thus the effects of the difference of manufacturing process, mixing proportion, porosity, and grain structure on the anomalous polarization of samples are examined. For example, as the spontaneous polarization of $BaTiO_3$ is believed to be a few μc/cm², such a sample as no. *108* in Fig. 2, which has a large value of P_r, must be considered to have large anomalous polarization. But no. *102* does not seem to have so large anomalous polarization. The values of P_i in Table I are calculated as follows: By extending the straight-line portion of the curve which shows the relation between P_r and t in Fig. 3, P_{r0} is obtained from the intersection of the straight line with the ordinate. P_i is calculated by substructing P_{r0} from the value of P_r at 20 minutes on the abcissa.

Effect of Manufacturing Process

Fig. 2 shows the results of various samples of different manufacturing processes, in which no. *109* has a very long mixing time of 50 hours, no. *108* has a very long baking time of 4 hours, and no. *110* is sintered for 2 hours at 1,450 C. Such variety in manufacturing process does not seem to cause any substantial difference on anomalous polarization. No. *102* does not seem to show any anomalous phenomenon. This sample is immediately sintered at 1,400 C without going through the previous baking.

Porosity

Since ceramics are generally very porous the effect of the internal surface of the pores on anomalous polarization is measured. The sample no. *102* is much more porous than no. *101* as shown in Fig. 4. Nevertheless, no. *102* does not seem to have any anomalous polarization as indicated in Fig. 2. Therefore porosity may have no direct effect on anomalous polarization.

Mixing Proportion

The mixing proportion of $BaCO_3$ and TiO_2 seems to have a considerable effect on the anomalous polarization. No. *104* and no. *106* in Fig. 5 which have excess TiO_2 amounting to 1 and 3 mole per cent respectively show large anomalous polar-

Table II.

No.	Composition	Curie Temperature, C	20 C	Curie Temperature	tan (10^{-4})	(10^{10} cm)	(μc/cm²)

D—No. 106, ×133

ization. However no. *103* and no. *108* which have excess $BaCO_3$ amounting to 1 and 3 mole per cent respectively show very small anomalous polarization.

GRAIN STRUCTURE

Applying metallurgical techniques to the polish and corrosion of ceramics, Kulcsar[3] observed the crystal structure of the ceramics. He reported that considerable growth of crystal had been observed in a sample having excess TiO_2 and just the reverse in a sample containing excess $BaCO_3$. In this paper a number of samples are examined by the same method as Kulcsar's. As shown in Fig. 4(D), sample no. *106* with excess TiO_2 contains larger grains of crystal than no. *101*, Fig. 4(C). Although no samples having excess $BaCO_3$ are shown very fine grains of crystal are always present.

Considering the result obtained in the preceding paragraph, a sample exhibiting marked growth of crystal, i.e., having small grain boundary such as no. *106*, shows large anomalous polarization, and a sample which contains fine crystal such as no. *105* shows small anomalous polarization. This fact indicates that grain boundary does not seem to contribute much to the anomaly; i.e., free ions wandering through the grain boundary do not seem to play any leading role in anomalous polarization.

Nature of Anomalous Polarization

As it is not easy to separate P_i (anomalous polarization) from P_s (spontaneous polarization) definitely it is difficult to know the nature of P_i accurately. However, as the spontaneous polarization of $BaTiO_3$ ceramics is believed to be a few $\mu c/cm^2$ the amount of P_i can be derived approximately as follows.

TEMPERATURE CHARACTERISTIC OF ANOMALOUS POLARIZATION

Fig. 6 shows the change of P_r of $BaTiO_3$ referring to the time-of-voltage impression with ambient temperature as a parameter. From these results it is easily understood that the higher the temperature rises the larger the anomalous polarization grows. In Fig. 7 the ordinate represents the logarithm of the inclination of straight-line portion of each curve in Fig. 6, and the abscissa shows the parameter of the curves in Fig. 6 measured by absolute scale. The relation is shown fairly well as a straight line.

Next, the characteristics of P_r near the Curie point are examined. As the Curie

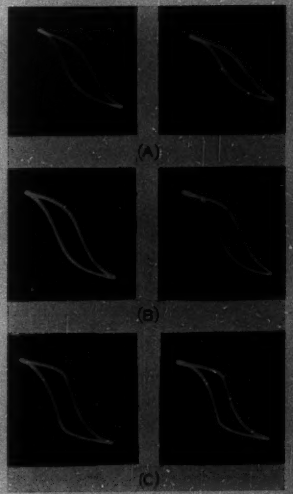

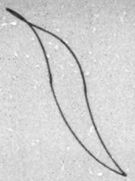

Fig. 13. Unsymmetry of hysteresis loop

point of $BaTiO_3$ is too high and inconvenient for the purpose of our experiment $(Ba\text{-}Sr)TiO_3$ ceramic is used which has a transformation point at 41 C. Fig. 8 shows the result of the experiment. Two straight lines obtained above the Curie point intersect the other two obtained below the point. This naturally is expected because of the nature of P_r which contains P_s below the Curie point.

DECAY OF ANOMALOUS POLARIZATION

Fig. 9 shows the decrease of residual polarization P_r in $BaTiO_3$ ceramics with the passing of time. After being polarized by impressing an electric field of 25 kv/cm for 5 minutes at 60 C, the sample is left at room temperature or at 60 C. Its residual polarization is then measured by the ballistic galvanometer at some selected time. As P_s may also change after some time it is impossible to show the characteristics of P_i accurately. However as the change of P_i is supposed to be comparatively small, as the measurement of the coupling factor shows, Fig. 9 is considered to show the decay of P_i approximately.

The regularity shown in Fig. 7 and the low rate of decay of P_r in Fig. 9 suggests that P_i may be caused by ions emigrating in the ceramics with small mobility.

INTERNAL ELECTRIC FIELD DUE TO ANOMALOUS POLARIZATION

A very interesting phenomenon is observed when P_r is measured in a sample polarized at a temperature above the Curie point. The polarized sample, which is connected to the measuring circuit beforehand, is cooled below the Curie point and then thrown into a paraffin oil bath heated to 170 C. An unusual deflection of the ballistic galvanometer is witnessed, it first deflects instantaneously a bit in the reverse direction and then in the normal direction. In order to verify the phenomenon the development of discharge in polarized ceramics is observed with the electromagnetic oscillograph. Fig. 10 shows the change of discharge current with time. Figs. 10(A) and (B) show the changes corresponding to the samples which have been polarized at 15 C by an electric field of 15 kv/cm and then dipped in a paraffin oil bath heated to 170 C. In the cases of Figs. 10(C) and (D), the samples are at first polarized at 60 C, at a temperature above the Curie point 41 C, then cooled to room temperature, and finally dipped in the heated oil bath. Evidently in Figs. 10(C) and (D) reverse currents are observed at the start of the discharge. Such a phenomenon can be interpreted as follows.

As a sample polarized at a temperature above the transformation point does not have spontaneous polarization P_s but only anomalous polarization P_i, an internal electric field due to P_i will predominate after the removal of the impressed field. This internal field may cause spontaneous polarization when the sample is cooled below the Curie point. The direction of such spontaneous polarization must be opposite to the initial polarization caused by the impressed field. Therefore, if the sample is heated above the Curie point again P_s may be depolarized at first rapidly and then P_i more slowly. The currents induced by them must be opposite in direction to each other. Thus the development of the discharge current should be observed in such a case as is shown in Figs. 10(C) or (D). Moreover the magnitude of P_s caused by the internal field can be evaluated from the deflection of a ballistic galvanometer. The value of P_s thus determined is about 1.8 $\mu c/cm^2$.

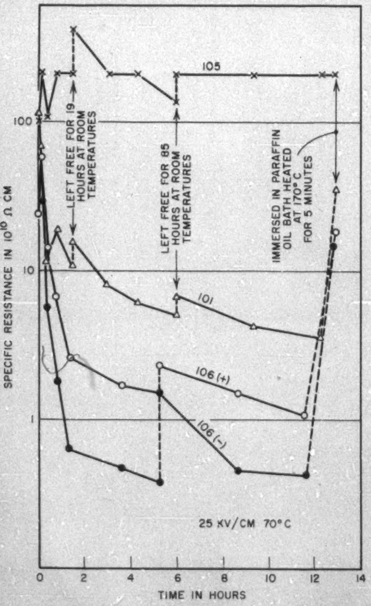

Fig. 14 (left). Change of specific resistance with time-of-voltage impression in $BaTiO_3$ ceramics

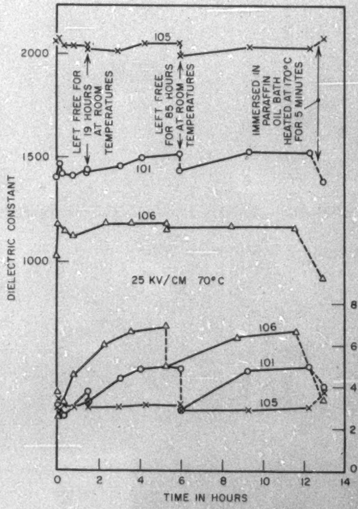

Fig. 15 (right). Change of dielectric properties with time-of-voltage impression in $BaTiO_3$ ceramics

Accordingly it is imagined that the anomalous polarization has a considerable effect on the spontaneous polarization in this way.

RESIDUAL POLARIZATION IN A SINGLE CRYSTAL OF $BaTiO_3$

Fig. 11 shows the relation between the time of impression of the electric field and the result, residual polarization (P_r) of a single crystal of $BaTiO_3$. The crystal is grown in a salt bath having potassium fluoride. Anomalous polarization does not seem very large in this case.

HYSTERESIS LOOP OF POLARIZED SAMPLES

Fig. 12 shows hysteresis loops of polarized $BaTiO_3$ ceramics and a single crystal under various conditions. Sawyer-Tower's circuit is employed in the measurement. The impressed electric field is 20-kv/cm at 50 cycles per second. Although a polarized ceramic shows an unsymmetrical hysteresis loop (Fig. 13), a single crystal seems to keep a symmetrical loop at all times. Such unsymmetry as shown in Figs. 12(A) and (B) is thought to be ascribed to the internal electric field caused by the anomalous polarization as already explained in the previous paragraph.

CHANGE OF RESISTIVITY AND OTHER DIELECTRIC PROPERTIES CAUSED BY ANOMALOUS POLARIZATION

No. *101*, no. *105*, and no. *106* are the samples which have different grades of anomalous polarization from one another. The change of resistivity and other dielectric properties versus time-of-voltage impression are measured for these samples and the results are obtained as shown in Figs. 14 and 15. Although no. *105*, having comparatively small anomaly, shows almost no change in these properties, no. *101* and no. *108*, having large anomaly, show considerable change in resistivity and tan δ. If these samples are left free at room temperature their properties are recovered to some extent as shown by short vertical dotted lines in Figs. 14 and 15. If they are dipped in an oil bath at 170 C for 5 minutes they are recovered nearly to the initial state. As one can see from the result of no. *106* in Fig. 14, resistivity depends more on the polarity of the measuring voltage as P_r grows larger. In these figures a curve having a plus sign shows the resistance measured by applying potential in the same direction as polarizing potential, and another curve having a minus sign is the reversed case. Such different features are also caused by the internal electric field which is built up by the anomalous polarization.

CHANGE OF THE COLOR OF SAMPLES ACCOMPANIED BY ANOMALOUS POLARIZATION

One of the most interesting phenomena accompanying anomalous polarization is the change in the color of the samples. Those samples which show large anomalous polarization change their color from yellowish white to brownish black gradually if they are impressed with a considerably high voltage. But those which do not show anomaly do not change their color at all. If a throughly colored sample is broken in pieces it is found that the interior of the sample has been uniformly tarnished. Even though such a sample is left as it is for a fortnight, the tarnish hardly changes. But it is faded thoroughly when the sample is heated at 170 C for about 10 minutes. Such change of color is thought to indicate some chemical change which has occurred in the sample. This color change resembles that which accompanies the reduction of titanium oxide. Hence anomalous polarization may be caused by some chemical change.

Considerations

Judging from the velocity of its birth and death and also from the temperature characteristics of anomalous polarization, it is almost certain that the phenomenon is caused by the movement of ions. Although it cannot be explained by the action of ions moving along internal surface or grain boundary in ceramics, it may be attributed to some internal defect of the crystal. The phenomenon is not affected by the porosity and grain size of crystals in ceramics. On the other hand, the change of color in a sample accompanied by anomalous polarization proves the occurrence of some chemical change in the crystal. From these facts it might be inferred that the anomalous polarization could be caused by the reduction of Ti in the sample or by the effect of the increased defects of oxygen. A phenomenon resembling the one described was found earlier in TiO_2 by Tago and Watanabe.[4] They investigated the cause of the decrease of insulation resistance and the increase of dielectric loss in a TiO_2 condenser by impressing an electric field and concluded that these phenomena should be attributed to the reduction due to the impressed field which would remove oxygen ions at lattice points in the crystal. Breckenridge and Hosler[5] examined the mechanism of electric conduction in TiO_2 which was partially reduced in hydrogen atmosphere and inferred that some Ti ions were reduced from four to three in valence and, accordingly defects of oxygens should be the result.

Although Blood and his co-workers[3] found an anomalous property of $BaTiO_3$ they attributed it to the state of surface of the crystal to which Könzig and others had alluded. (Könzig[6,7] was of the opinion that the state of the surface layer of $BaTiO_3$ crystal, about 100 Angstroms deep, differs from the interior. The crystal is heavily strained in the layer up to the temperature several hundred degrees centigrade above the Curie point and the strain is caused by the electric field due to the space charge in the surface layer.) But if attention is focused on the considerably large reverse electromechanical activity observed by Blood and others, and also the large inverted spontaneous polarization caused by the internal electric field observed by the authors, it would be more appropriate to attribute the anomaly to the movement of ions through the crystal instead of to the state of the surface layer.

It is very interesting that the anomaly depends to a great degree on the mixing ratio of $BaCO_3$ and TiO_2. When the ratio differs from unity, Ba_2TiO_4, $BaTi_2O_5$, etc., in addition to $BaTiO_3$ might be produced as reported by Kubo,[8] Roy,[9] and others. However, these compounds are all nonferroelectric material. Therefore, if consideration is given to the relation between the anomalous polarization and the spontaneous polarization mentioned in the preceding section, such products are hardly thought much of as the main root of the anomalous polarization. It is more appropriate to consider that the excess or insufficiency of Ti or Ba has a marked influence on the stability of a crystal.

Conclusions

A series of experiments executed on the abnormally large residual polarization in barium titanate is not interpreted by proper spontaneous polarization. It is inferred that the anomaly may be attributed to the movement of vacant holes of oxygen caused by the reduction of Ti in the crystal. It is also explained that the anomalous polarization is remarkably affected by the mixing ratio of $BaCO_3$ and TiO_2.

As anomalous polarization has direct influence on spontaneous polarization and as it causes the decrease of insulation resistance and the increase of tan δ, it should be considered when the ferroelectric substance is to be managed.

Factors Leading to the Development of Ceramic Hydrogen Thyratrons

A. W. COOLIDGE
MEMBER AIEE

HYDROGEN THYRATRONS are used as switching tubes in line-type pulsers in most high-power radar equipment.[1,2] A lumped-constant transmission line is repetitively charged to a high voltage and discharged by firing the hydrogen thyratron to provide pulses of power to the radio-frequency oscillator tube. The transmission time of the resulting high-frequency pulses to the object scanned and back to the receiver is the mechanism by which distances are measured by the radar equipment.

Development work was started on the hydrogen thyratron in 1941. The use of hydrogen as a gas filling presents several advantages for this service:

1. A high arc drop or cathode fall of potential at high peak current can occur without injury to the oxide cathode. Approximately 600 volts can be tolerated in hydrogen, compared with 30 volts in mercury vapor.
2. A short deionization time is attained in hydrogen, permitting high pulse-repetition rates.
3. It has a high dielectric strength at low pressures.

A line of glass tubes now exists, consisting of seven basic sizes covering the range of peak and average power levels: from 10 kw peak and 25 watts average power to 33 mw (megawatts) peak and 33 kw average power. The essential ratings of these tubes are shown in Table I and the general appearance of a typical glass hydrogen thyratron is shown in Fig. 1.

The trend in tube requirements is toward higher peak and particularly toward higher average-power levels. The necessity for higher power radar equipment is occasioned by the need for detection and measurement at increasingly greater distances in view of the advances in speed of manned aircraft and the advent of guided missiles and nuclear weapons.

Switch tube development has not kept pace with the advancement in the high-frequency oscillator tubes. Former designs in hydrogen thyratrons do not readily lend themselves to great extension beyond present power levels. Since switching tubes of power capacity equal to that of the high-frequency tube are required in each application, a very great need for a basically new design in this field has arisen. The ceramic hydrogen thyratron, with external anode and grid elements, promises to fulfill this need.

Application Background

The elementary circuit of a radar modulator is shown in Fig. 2. The pulse-forming network is charged from the d-c power supply through the charging reactor. It is discharged through the load when the thyratron is triggered.

The charging reactor is a nondissipative element and permits the pulse-forming-network voltage to reach a value in excess of the power-supply voltage. Efficiencies approaching 100% may be obtained in a hydrogen-thyratron modulator using this circuit. The charging reactor and the total capacitance of the pulse-forming network combine to form a resonant circuit. The values of these elements are so chosen that their resonant frequency is usually, but not necessarily, equal to one half the repetition rate at which the modulator is designed to operate. Under such conditions, resonant charging prevails, and current and voltage relationships in the circuit exist as shown in Fig. 3. Charging current appears a series of positive half-cycles of a sine wave while the thyratron voltage appears as a series of half-cycles of a cosine wave swinging about the d-c power-supply voltage as an axis.

When the thyratron is triggered, the shape and amplitude of the discharge current are determined by the circuit constants of the network and load. A theoretical pulse-current wave shape is shown on an expanded scale in Fig. 4. The pulse width is usually set between the extremes of a few tenths of a μsec (microsecond) to several μsec.

The peak inverse voltage existing after the pulse-forming network is discharged aids in deionizing the thyratron, and its amplitude, assuming there is no clipping of the inverse voltage by means of a diode, depends upon the relative impedances of the pulse-forming network and the load. Equations illustrating this and other circuit relationships are given in the Appendix.

Internal Heat Dissipation

The internal heat dissipation in conventional thyratron tubes in rectifier or control service occurs mainly as power delivered to the gas and is equal to the average current multiplied by the tube drop. In the case of hydrogen thyratrons, additional power dissipations which become the ruling factors in tube design occur as a result of the rapid rise and fall of anode current and the high voltages appearing at the initiation and at the cessation of the pulse current.

ANODE DISSIPATION

The voltage, current, and power relations at the beginning and end of the pulse are shown on a greatly expanded time scale in Fig. 5. A peak of power dissipation occurs at the beginning and at the end of each conduction period. Although the time duration of these power pulses is very short (milliμsec) their instantaneous peak is in the mw range and they are repeated hundreds of times per second. The peak anode voltage, peak anode current, and pulse-repetition rate are the major circuit factors which determine anode heating, and their product is the tube rating which appears as the anode dissipation factor in Tables I and II.

At the beginning of the pulse, the rise of current is so rapid, in the order of 10,000 amp (amperes) per μsec, that relatively high anode voltage is required to establish sufficient ionization to support the required current. Consequently, the fall of anode potential from peak forward voltage to arc-drop voltage requires an appreciable time. The resulting power dissipation is very high and, in fact, is the major contribution to anode heating.

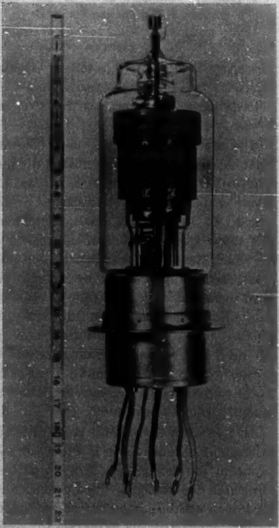

Fig. 1. GL-5948 hydrogen thyratron

At the end of the pulse, an appreciable ion current flows to the anode from the plasma after conduction in the forward direction ceases and inverse voltage is applied. Currents in the order of 50 to 100 amp have been observed in large tubes. An inverse voltage as high as 10 kv appears at the anode at the same time, resulting in a pulse of power dissipation in the tube.

In addition to these peaks of dissipation, which may be considered as the primary sources of anode heating, there is a secondary source which may assume appreciable values. Electrons emitted from the grid may flow to the anode without causing voltage breakdown and gaseous conduction. This is because the distance between anode and grid is in the order of the mean-free path of the gas and the probability of ionization is low. While the resultant currents may be in the milliampere range, the power dissipated can be high since the electron-accelerating voltage is the network forward voltage which becomes as high as 30 to 50 kv during parts of the charging cycle. In addition, the current flows essentially throughout the interpulse interval.

GRID DISSIPATION

The power delivered to the gas in the steady discharge is distributed to the electrodes surrounding the discharge. The greater portion of this is delivered to the grid because of its large exposed area. It is approximately equal to the average current multiplied by the tube drop.

CATHODE DISSIPATION

Because of the extremely high peak currents, 1,000 to 2,500 amp, and correspondingly high rms currents, the dissipation in the cathode results largely from the passage of the emitted electron current through the resistance of the coating. Its principal effect is to heat the cathode, which increases the rate of evaporation of active material and causes depletion of the coating.

General Design Considerations

The hydrogen-thyratron design reflects the unusual operating conditions in pulse switching service:

1. Extremely high peak current and voltage levels.
2. Current pulses in the μsec range with attendant high rates of current rise and fall.
3. High repetition rates with correspondingly short lengths of time available for recovery of the control function of the thyratron.
4. Rapid application of high inverse voltage to the anode in presence of very high levels of residual ionization.

A cross section of a typical high-power hydrogen thyratron of present design is shown in Fig. 6. The tube is approximately 6 inches in diameter and 16 inches long and is rated at 12 mw peak and 12 kw average power. Its envelope is of conventional glass design with tungsten lead seals for supporting and making connections to the internal elements. The anode is a large disk supported from a lead at the top of the tube. Molybdenum is used for the anode to withstand the severe ion bombardment which occurs after

conduction when high inverse voltage is rapidly applied to deionize the grid-anode space.

The hydrogen pressure within the envelope is established initially at as high a level as possible to minimize anode heating and to minimize the effects of gas clean-up during the life of the thyratron. In view of the high pressure, anode-to-grid spacings are made very small for high-voltage operation. The voltage breakdown between two electrodes in a gas follows the well-known curves of breakdown voltage versus the product of pressure and distance (Paschen's Law). The curve for mercury shown in Fig. 7 is typical for gases commonly used in tubes. It extends well into the left-hand region for which no values for hydrogen are published. The grid-anode space in the thyratron is such that the operating points are in this region where the breakdown voltage is rising rapidly as the product of pressure and spacing is reduced. At a given pressure, the voltage at which breakdown will occur depends upon the longest path between grid and anode over which a discharge will take place.

In view of this, the small distance from grid to anode must be maintained throughout and the grid structure is designed to surround the anode completely. Long-path discharges at the anode stem are prevented by surrounding the stem with a glass cylinder which fits into a metal sleeve in the grid structure. The anode structure becomes more complex in the larger tubes which operate at higher voltages and at higher temperatures. Additional members, as illustrated in Fig. 6, are required to reduce voltage gradients and to avoid conduction through the glass at high temperature. Such conduction might complete the electrical path necessary to form a long-path discharge.

Hydrogen thyratrons are designed with a positive control characteristic and differ from most thyratrons in this respect. This simplifies the grid-trigger circuit in that no grid bias is required. In addition, the amount of baffling associated with the positive characteristic minimizes grid-emission difficulties. In order to achieve these characteristics, the baffling between cathode and grid shown in Fig. 6 is introduced. The grid itself is a perforated or slotted disk and the baffles underneath it are solid.

The cathode is a conventional, oxide-coated, indirectly heated type with sufficient area to furnish the peak emission and to conduct the required rms current through the coating without raising its temperature beyond the permissible limit. This limit is a function of its evaporation rate versus temperature and the expected life.

Average power output (kw)	66	44	200	400
Anode dissipation factor (peak voltage × peak current × pulse repetition rate)	40×10^9	45×10^9	400×10^9	800×10^9

The disappearance of gas from an enclosed container in which an electrical discharge is present is familiarly known as clean-up. It is recognized that various processes contribute to the over-all result.

In noble gases, it has been shown[4] that clean-up occurs as a result of the impact of positive ions upon electrodes at considerable negative potentials with respect to the source of ions. Sometimes the noble gas ions stick in the electrode to which they have been accelerated. At other times, apparently, they are neutralized there and leave with enough velocity to cause them to stick on adjacent surfaces. Sputtering of electrode metal on to other surfaces may enhance the clean-up by continually providing fresh surfaces and also by mechanically carrying and trapping the gas.

In hydrogen thyratrons these mechanisms undoubtedly occur, but they are not alone in producing the effect. The hydrogen is dissociated in the arc to atomic hydrogen which is extremely active chemically. This may be expected to cause clean-up by chemical action[5] or by diffu-

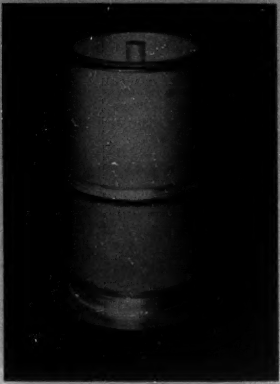

Fig. 8. Developmental ceramic hydrogen thyratron Z-5069

sion through certain materials forming the boundaries of the arc.

The mechanisms of gas clean-up become sufficiently severe in high-power hydrogen thyratrons that a hydrogen replenisher or pressure-maintaining "reservoir" has been developed for these tubes. It consists of a quantity of titanium or zirconium hydride held at an elevated temperature by an auxiliary filament. The hydride dissociates according to the reversible reaction:

$$T_iH_2 \rightleftarrows T_i + H_2$$

The equation moves to the right or left depending upon the temperature of the hydride, the concentration of the hydrogen remaining in the hydride, and the pressure of hydrogen above the hydride. A hydrogen reservoir provides a means for deriving the optimum pressure for tube operation and is a replenishing source for minimizing the effects of hydrogen loss.

With the reservoir characteristics known, the pressure range over which the tube will operate successfully can be determined by varying the voltage applied to the reservoir filament. The voltage range over which successful operation is attained is usually referred to as reservoir range. With a given reservoir characteristic, its width provides a measure of the performance margin at a given level of operation. The range is most accurately presented as a percentage of the center or optimum operating point.

The upper end of the operating pressure range and hence the upper end of the reservoir range is a function of voltage breakdown and of recovery time. As previously indicated, thyratrons operate to the left of the minimum point of the curve shown in Fig. 7 and, with a given electrode spacing the voltage, breakdown occurs at progressively decreasing levels with increasing pressure.

Either of several criteria may determine the lower end of the operating pressure range. The amount of ionization from the trigger pulse required to initiated conduction to the anode within the specified anode firing time and within the specified variation in successive firing times, "jitter," increases with decreasing pressure. Pressures below an approximate value of 200 microns make it impossible for anode conduction to take place at all.

The establishment of sufficient plasma density to support the required rate-of-rise in anode current and the ultimate peak value of anode current becomes increasingly difficult with decreasing pressure. The voltage required to establish and maintain the plasma rises accordingly and anode dissipation rises rapidly. Excessive anode heating is the most common factor limiting the lower end of the pressure range.

Ceramic Hydrogen Thyratrons

The ceramic hydrogen-thyratron design provides greater reservoir ranges at present power levels and acceptable ranges at greatly extended power levels. The *Z-5069* developmental tube is shown in Fig. 8. The tube is approximately 5 inches in diameter and 10 inches tall. The objective ratings are 33 mw peak and 66 kw average power. The internal construction is shown in the cross-sectional drawing, Fig. 9. Both anode and grid consist of cups with extended flanges brazed directly to the ceramic cylinders which form the envelope and provide the insulation between elements. The cathode is supported from a header brazed into the bottom of the ceramic envelope.

Extension of the lower end of the reservoir range at high average-power levels is accomplished in several ways. Because it is external to the tube and is convection rather than radiation cooled, the heat-dissipation capacity of the anode is an order of magnitude greater than in internal anode designs. In addition, the design lends itself very readily to forced liquid cooling for still greater heat-dissipation rates.

The reduction in grid temperature is twofold. More cooling is provided by the external flange and its connection to the envelope, and less heat is radiated to it from the relatively cool anode. The dissipation at the anode is further reduced by the reduction in electron current emitted to it from the grid because of the lower grid temperature.

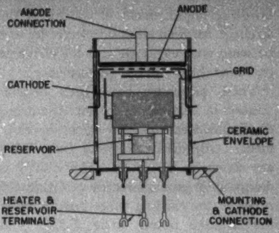

Fig. 9. Cross-sectional view of developmental ceramic hydrogen thyratron Z-5069

Extensions in the upper end of the pressure range affect the average power level mainly by raising the permissible anode voltage. These occur chiefly because of improved high-voltage operation afforded by the simple planar construction in the anode-grid area. The spacings between the cylindrical surface of the anode and grid and the corresponding ceramic surfaces are less than the mean-free path of the gas. Electrons in this space are much more likely to be accelerated to a near-by surface than to cause ionizing collisions with gas molecules. Thus, the probability of ion formation in this area is extremely low and subsequent long-path discharges are prevented. Voltage-breakdown levels between grid and anode near the theoretical value for the spacing between them are thus achieved.

The ceramics are dimensionally very accurate since they are ground to size. The method of assembly, wherein the elements are stacked and brazed together, preserves and utilizes this accuracy. The

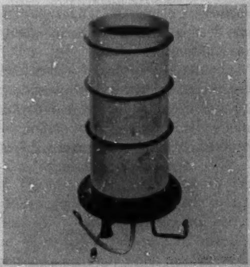

Fig. 10. Developmental ceramic hydrogen thyratron having one gradient grid, Z-5101

resulting improvement in control of the spacings between adjacent electrodes and between each electrode and the envelope enhances high-voltage performance.

These principles have been demonstrated in ceramic hydrogen thyratrons of extended ratings now under development. Objective ratings for these tubes are shown in Table II. The *Z-5069* is designed for peak power levels within the range of the existing tubes but for twice the average power. The *Z-5101* and *Z-5212* represent the first two phases in a co-ordinated program to provide progressively larger sizes in terms of both peak and average power. The developments of the *Z-5069* and the *Z-5101* are substantially complete. The development of the *Z-5212* will, when completed, form the basis for extension to the third or final phase of the current program.

Successful operation and acceptable reservoir ranges have been achieved at the objective power levels. Life tests are being conducted to the limit of existing test equipment. Paralleling of the largest available test equipments in pairs will provide sufficient power on a continuous basis for extensive life-test evaluation at full ratings.

The *Z-5101* has been successfully operated at peak anode voltages to 50 kv while switching a peak-output power level of 75 mw. Performance at this and higher voltage levels, as in phases II and III of the current development program, is facilitated by the use of voltage-dividing or gradient grids. The anode voltage is divided between the tube sections thus formed by means of external circuitry or simply by the internal capacitance between the elements. The voltage between adjacent electrodes is thereby reduced to values at which adequate safety margins are attained. A *Z-5101* with one voltage-dividing grid (two sections) in addition to the usual control grid is shown in Fig. 10. The stacked or building-block type of structure in the ceramic-envelope design lends itself admirably to the inclusion of these additional elements.

Comparatively high mechanical strength and rigidity and correspondingly improved tolerance for shock and vibration are also features of this construction. These are especially important in view of the almost exclusive application of these tubes in military service.

PROBLEMS IN FURTHER EXTENSION

As the tube ratings increase, anode dissipation becomes a greater problem. Great increases in anode size have doubtful value in view of the probability of decreased utilization of the total area of both anode and grid. Consequently, further increases in power levels to phases II and III will probably required forced liquid cooling of the anode and possibly the grid.

Hydrogen clean-up becomes increasingly severe as power levels are raised. A solution of the basic problem must be found or the use of larger reservoirs or maintenance of tube pressure by a regulating means employing a reservoir and a monitoring device must be employed.

With forced cooling the size of the envelope may be determined by the cathode area rather than by the anode-and-grid structure. New types of cathode coatings are being evaluated to provide sufficient emission in smaller sizes. These coatings will have lower internal resistance than the conventional oxide coating and, therefore, there will be less heating by conduction losses.

Conclusion

Performance tests indicate that the ceramic, external anode-and-grid design permits extension of hydrogen thyratron ratings to the desired objectives. Thus, ceramic hydrogen thyratrons will provide the required switching capacity for contemplated higher-power radar equipment.

Appendix

Simple relations are given for the following: 1. inverse voltage, 2. forward voltage, 3. peak current. 4. average current. 5. peak power., and 6. average power.

Some of the following equations are approximations and depend on these assumptions: 1. There is no clipping of the inverse voltage by means of a diode. 2. There are no losses in the charging circuit or in the hydrogen thyratron.

Inverse voltage:

$$e_{px}=e_{py}\frac{Z_0-R_L}{Z_0+R_L}$$

where

e_{px} = peak inverse voltage
e_{py} = peak forward voltage
Z_0 = characteristic impedance of pulse forming network
R_L = load impedance reflected at the primary of the pulse transformer

Forward voltage:

$$e_{py}=2E_{dc}+e_{px}=E_{dc}\frac{Z_0+R_L}{R_L}$$

where

E_{dc} = d-c power supply voltage

Peak current:

$$i_p=\frac{e_{py}}{Z_0+R_L}$$

where

i_p = peak anode current

Average current:

$$I_p=i_p\times t_p\times p_{rr}$$

where

I_p = average anode current
t_p = pulse width
p_{rr} = pulse repetition rate

Peak power:

$$P_{pk}=E_{dc}\times i_p$$

where

P_{pk} = peak power delivered by the modulator to its load

Average power:

$$P_{avg}=E_{dc}\times I_p$$

where

P_{avg} = average power delivered by the modulator to its load

Electromechanical Impedance: Analogs and Duality

WAYNE B. SWIFT
ASSOCIATE MEMBER AIEE

IT IS FELT that 4-terminal network theory is potentially of great value in the analysis of problems in the non-electrical realm and problems which are only partially electrical. In attempting to apply 2-port theory however,[1,2] some perplexing difficulties arise. These appear to the author basically to be due to somewhat loose habits of thought in defining impedance and admittance on the basis of purely electrical concepts without due regard for their significance in other domains.

The purpose of this discussion is to present a re-examination of the concept of impedance and to suggest a consistent criterion for impedance character. This requires careful specification of network variables. It is found on topological grounds that there is a natural correspondence between current in an electric system and force in a mechanical system. The use of this fact allows us to determine whether a given lossless device is properly considered as an ideal transformer or as a gyrator and whether a given parameter is properly considered as an impedance, an admittance, or as an h-parameter.

Finally, it is pointed out that the curious differences between the all-electric equivalent-circuit behavior for magnetic transducers and electrostatic transducers appear because one is, properly speaking, an ideal transformer and the other is, properly speaking, an ideal gyrator.

Definition of Network Variables

A self-immittance is a ratio between two variables of a network element which are so chosen that at least the following two conditions apply: 1. their product is power; and 2. either is convenient for use in establishing the contribution of the element in question toward system equilibrium. The second of these conditions suggests that an equilibrium principle should pertain to each of the two variables so used. Equilibrium can always be guaranteed in a network configuration by writing equilibrium equations which result from a systematic choice of one sort of variable in terms of the other. In an electric network, for example, mesh current equations can be written to express voltage equilibrium, the current equilibrium conditions being automatically satisfied because of the systematic choice of the currents. These equations represent a condition of equilibrium about a topologically doubly (at least) connected region, i.e., about a mesh of the network.

No amount of information at any particular point can possibly suffice to give all the information which is needed to state the equilibrium conditions around any mesh. For this it is necessary to imagine a complete traverse of a boundary of a multiply connected region, something which, by definition, is not reducible to a point. A formally similar equation can be written, however, if we first obtain the dual of the original network (this presumes that the original network was planar). Then a node-voltage equation of identical form is written by establishing current equilibrium at a point. The equation asserts the existence of this equilibrium at the point which is the node.

This discussion has suggested that a third condition on the variables to be used is that they must be of the nature of duals of one another, and this means that one must achieve equilibrium about a mesh while the other achieves equilibrium at a point.

The conditions on the two variables used to define immittances may then be restated: 1. one (e.g., m) obeys an equilibrium condition about the mesh; 2. the other (e.g., n) obeys an equilibrium condition at the node; and 3. the instantaneous product mn yields power into the element being considered.

The value of either m or n in an element is known from the properties of the element whenever the value of the other variable is known.

It is customary to express this fact in the form of defining relations of the form of equation 1

$$Z=\frac{m}{n} \quad Y=\frac{n}{m} \tag{1}$$

where all symbols are considered as in general operational quantities.

Mechanical Networks and Electrical Analogs

In electric network analysis, it is clear that the m variable is voltage while the n variable is current. But in the electrical domain there has never been any particular confusion over the question of whether a given ratio is an impedance or an admittance; it has appeared to be obvious. In the mechanical domain, however, it had been taken for granted for a long time that force was a variable which directly corresponded to voltage and all equivalent circuits were based on this assumed correspondence. It was not until relatively recently that it was pointed out by Firestone[3] that other equivalent circuits could be evolved using current and force as corresponding variables. The question of whether or not voltage-force was the only allowable analogy was settled by the discovery of Firestone's "mobility" analog, but only at the cost of raising other and perhaps more serious questions. Of the two analogs available, was either of them a "true" one? If so, which one? Why did the current-force analog preserve the topology of the mechanical system for a magnetic transducer but not for an electrostatic transducer? These questions are fundamental to a consideration of the reciprocity of the systems which are not purely electrical.[4] Using the force-voltage correspondence for a d-c motor, the z-matrix turns out to have opposite signs on the z_{12} and z_{21} elements and is therefore termed antireciprocal. Using the force-current correspondence, however, the z-matrix turns out to be symmetrical. The device has not changed, only the observer's point of view has shifted. Yet, if the self-impedances are neglected, in one case the device is an ideal transformer while in the other it is an ideal gyrator.

Ideal Transformers and Gyrators and Corresponding Variables

Investigations of the z-matrix and the h-matrix of the transducers are perhaps the most suggestive way of attacking these questions since the results tend to parallel those which appear for ideal elements in the purely electrical domain.

Paper 58-529, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Great Lakes District Meeting, East Lansing, Mich., May 5–7, 1958, and re-presented at the Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted March 28, 1957; made available for printing October 22, 1958.

WAYNE B. SWIFT is with The University of Wisconsin, Madison, Wis.

An ideal transformer, for example, has no proper z-matrix. All elements in the matrix are infinite unless external elements, unconnected with the essential mode of operation of the transformer, are included to furnish spurious interdependences between properly independent quantities. If an ideal transformer is attacked in any way such as to suggest that its z-matrix is well behaved, then there must be something odd and improper about the approach used. Its h-matrix is perfectly well behaved, however. An ideal gyrator, on the other hand, is characterized by a well-behaved but antireciprocal z-matrix; its h-matrix contains only infinite components. Thus, when a device called a gyrator is shown to have a normal h-matrix but an ill-behaved z-matrix, it is certain that the approach to the problem was unnatural and somehow improper.

As an example of the sort of improper throught process which can be imagined in this regard, one may suppose that the quantities of primary voltage and secondary current were regarded as corresponding to the m variables. Then the "impedance" matrix could be written as shown:

$$m = zn = \begin{bmatrix} m_1 \\ m_2 \end{bmatrix} = \begin{bmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{bmatrix} \begin{bmatrix} n_1 \\ n_2 \end{bmatrix} \qquad (2)$$

Now the elements of this matrix will be as follows, if the self-impedances are ignored:

$z_{11} = 0$

$z_{12} = 1/a$ (turns ratio)

$z_{21} = -1/a$

$z_{22} = 0$ (3)

There are two things seriously wrong with this z-matrix for an ideal transformer: First, it is antireciprocal despite the fact that an ideal transformer is well known to be a reciprocal element, and second, it is well behaved instead of containing only infinite elements as the z-matrix of an ideal transformer should. The conclusion is that the choice of m_1, m_2, n_1, n_2 as e_1, i_2, i_1, e_2, respectively, is improper and unnatural since such a choice leads to elements of the z-matrix which are not dimensionally equivalent to an impedance. This is something which can be seen intuitively when purely electrical problems are considered.

Corresponding Electrical and Mechanical Variables

In the mechanical domain confusion exists since no one can be sure what impedance means. If the variables m and n are selected according to the rules already mentioned, however, the identity of mechanical impedance is at once established. Furthermore, such a procedure gives light on what ought to be done in the process of choosing corresponding variables at opposite ends of a transducer problem. Corresponding variables are those which have corresponding topological equilibrium equations. Thus, force, which obeys the condition of equilibrium at a point, takes on a likeness to current in the electrical realm. Velocity, which must be summed about a mesh of the mechanical system to express equilibrium, is likened to voltage. If this rule is followed, the resulting matrices for ideal elements fall into one of these two categories:

1. If the ideal element is truly an ideal transformer, its z-matrix will be ill behaved, but its h-matrix will be well behaved and antireciprocal.
2. If the ideal element is truly an ideal gyrator, its z-matrix will be well behaved and antireciprocal but its h-matrix will be ill behaved.

Transducers

It can now be pointed out that if the ideal electromagnetic transducer is considered under these rules, its h-matrix is well behaved and the off-diagonal elements are opposite in sign. This indicates a reciprocal element which is an ideal transformer. If the force-voltage choice of variables had been made, a well-behaved z-matrix would have been obtained with the antireciprocal character.

If the z-matrix is written for the ideal electrostatic transducer with proper choice of variables, i.e., with force-current correspondence, there results a well-behaved and antireciprocal matrix. Thus the electrostatic transducer is a gyrator. In order to include representations of the mechanical elements of the electric transducer in an over-all electric-system diagram, it is therefore necessary to include an ideal gyrator. If for any reason the gyrator is to be eliminated from the over-all diagram then it is necessary to take the dual of either the electrical or the mechanical portion of the over-all system (not both). This procedure yields an ideal transformer in the place formerly occupied by the gyrator. The custom has been to obtain the dual of the mechanical part of the system in these situations, and this procedure yields an apparent force-voltage correspondence. The process of obtaining a semidual configuration to rid the system of its gyrator effects is unnecessary for the magnetic transducer since this device contains no ideal gyrator. Hence the force-current analog yields an electrical equivalent of the mechanical part of a magnetic transducer which can be connected into the electrical part of the over-all diagram with no gyrator but still holds the original topology of the mechanical network.

It seems to the author that the better procedure in the case of the electrostatic network is to include the ideal gyrator specifically when indicating the diagram of the mechanical part of an electrostatic transducer in order to 1. maintain the original topology, and also 2. to force recognition that a true gyration has taken place. This is inescapable when the same electric circuit is made to feed two transducers, one electric, the other magnetic, whose mechanical elements are interconnected.

It is now possible to demonstrate the way in which the classical approach to electrical analog problems fails. This is usually not apparent because problems of such simplicity are used. For instance, a mechanical network having five nodes with ten elements linking the five nodes in all possible ways will result in a network that is not planar[5] and hence has no dual. For this reason it is impossible to draw an electrical equivalent circuit using the force-voltage analog unless obviously nonequivalent elements are used. In all such cases as this the mobility analog shows its true character since it can easily be drawn and since it reproduces the topology and the active or passive character of the corresponding elements of any network as well as formally identical equations.

The conclusion is, then, that the classical analog is a false one and that the force-current analog is the one true analog.

Conclusions

In analyzing any network element a pair of related variables must be used such that over-all system equilibrium implies equilibrium at a connection point in one variable n, and about a multiply connected region in the other, m. Impedance is then defined as m/n.

Application of this principle leads to the conclusions that:

1. Force and current are corresponding quantities.
2. A force-voltage analog in a transducer is artificial and requires introduction of an ideal gyrator and semidual topology into the equivalent circuit. This gyrator can

be eliminated only by taking the dual of one portion of the circuit. The whole process is impossible except on planar systems.

3. A transducer using an electric field as the coupling medium is in essence a gyrator; an over-all electrical equivalent circuit contains an ideal gyrator. Elimination of this gyrator requires obtaining the dual of one part of the circuit separated by the gyrator.

4. If a network containing one magnetic and one electrical transducer provides interconnections both electrically and mechanically, then its over-all diagram must contain an ideal gyrator.

The case of a nonplanar mechanical network is examined to test these conclusions and it is shown that an electrical equivalent circuit can readily be found provided force and current are regarded as corresponding quantities. But no electrical equivalent circuit exists if force and voltage are regarded as corresponding quantities, presuming that an equivalent circuit implies element-by-element correspondence. By this test, the validity of the force-current analog and the falsity of the force-voltage analog is confirmed.

Measurements of Narrow-Band Noise on Telephone Facilities in Connection with Analog Data

J. O. EDSON

R. K. TOWNLEY
NONMEMBER AIEE

THE RECENT GROWTH of automation and the handling of data by machines have resulted in a growing need for data communication between terminals separated by many miles. Both the trend toward decentralization of business and the tendency toward centralized data-processing centers have contributed to this need. One solution to the problem of providing effective data communication is to use the telephone network which makes the interconnection of almost any two points in the country feasible.

Facilities for the transmission of digital data are presently available.[1,2] However, many of the data sources are analog in nature. Also most of the transmission facilities are designed to handle analog signals. Thus, the transmission of analog data directly instead of converting to digital form could lead to more simple terminal equipment and should therefore be investigated.

The telephone network has been designed primarily for the transmission of speech in an acceptable and economical way. The acceptable limits for the various transmission characteristics of the telephone network have been chosen principally to meet this requirement. However, speech signals can tolerate surprisingly large distortions of varied sorts and still preserve acceptable quality. The question then arises: what limitations on the transmission of analog data are imposed by the telephone network? Also what direction should the design of special systems take so as to work in the environment of the speech network.

It is well known that the telephone plant has been adapted satisfactorily to a number of nonvoice uses. A partial list would include telemetering, facsimile, telephoto, radio network, standard frequency transmission, and digital data transmission. Each of these services posed some problems which have been solved satisfactorily.

A high-resolution narrow-band analog-data system, which was designed on the basis of the usually measured characteristics of voice facilities, was tested. The tests were performed over a variety of transmission facilities typical of those used in both the regular switched network and private-line service. Since the co-ordination with supervisory and switching systems was not studied, these results should be interpreted as referring only to private-line services. As a result of these tests it was found that, in some carrier telephone systems, side bands are generated which appear as narrow-band noise around a transmitted tone. While these side bands were sufficiently low in amplitude that they could hardly be detected by the human ear, they seriously affected the performance of the analog-data system under test. The measurements of this noise and ways of overcoming its effects are discussed.

Investigation of Analog-Data Transmission

An interesting example of analog-data transmission that has recently been studied is telewriting, which may be defined as the sending of handwritten messages over a transmission medium. Investigations have shown that satisfactory performance may be attained over three channels, each 10 cps (cycles per second) wide. Differential delay between any two of the three channels should be limited to ±4 milliseconds. Resolution of one part in 250 is required. This resolution implies a signal-to-noise ratio of 60 db (decibels) when provision is made for typical noise peaks encountered in white noise. The requirements of many other analog-data systems can be included within these limits when due consideration is given to the number of channels, bandwidth, and signal-to-noise ratio required.

The simplest method of deriving three data channels from a voice channel is to use double side-band amplitude modulation on three carriers suitably located in the voice band. However, consideration of the permissible signal levels and the expected noise levels indicates that a signal-to-noise ratio as low as 35 db would be

---

Paper 58-1241, recommended by the AIEE Data Communication Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting Pittsburgh, Pa., October 26–31, 1958, and re-presented at the Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted August 19, 1958; made available for printing December 3, 1958.

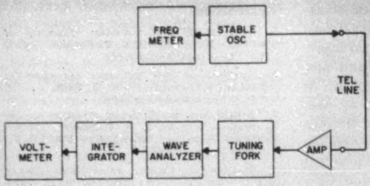

Fig. 1. Block diagram of narrow-band noise measuring system

frequently encountered. Thus, in order to achieve the required 60-db ratio, the use of frequency modulation seems indicated. A frequency-modulated wave, equal in amplitude to a fully amplitude-modulated wave, with a total deviation of ±52 cps will give the required additional 25 db advantage over noise.

A telewriting system which met the preceding requirements, was tested over various facilities. A sample representative of normal telephone transmission facilities was chosen for the tests.

Prediction of performance over each facility was made on the basis of noise measurements with the facility terminated. Readings were taken with a Western Electric Company *2B* noise meter.[3] For the compandored carrier-telephone system,[4] due consideration was given to the changes of gain within the system that are produced in the compandor by the presence of a tone.

In most cases, the performance of the telewriting system was in excellent agreement with the predictions based on normal measurements of the voice facilities. However, the performance was significantly poorer than predicted over types *N*, *O*, and *ON* carrier systems.[5,6] The *N*, *O*, and *ON* carrier systems were designed as inexpensive compandored systems and they make full use of the noise advantage the compandor gives on voice.

The most striking feature of the observed disturbance of the written message when using these carrier systems is its independence of large variations in subcarrier amplitude. This suggests that the disturbing signal maintains a constant relationship to the subcarrier and manifests itself only while the carrier is present. Preliminary tests indicated that the mechanisms involved are apparently frequency insensitive. That is, the noise spectrum about the test signal preserves its shape as the signal is varied over a narrow range.

MEASURING EQUIPMENT

Consideration of the magnitude and location of signals that can cause the observed disturbance leads to the following requirements on the measuring equipment:

1. Selectivity giving approximately a 1-cps bandwidth.
2. Selectivity capable of resolving products 50 to 60 db below a test tone over a band 10 cycles on either side of the test tone.
3. Provision for approximately 100 db dynamic range.
4. Stability over periods sufficiently long to allow a series of measurements to be made without readjustment.
5. Integration of the detected output sufficient to provide a reasonable estimate of the noise.

A block diagram of the test setup is shown in Fig. 1. It consists of a stable oscillator whose frequency can be varied with precision over the band of interest. A tuning fork and wave analyzer provide the required selectivity and sensitivity. The integrator and d-c vacuum-tube voltmeter make a reasonably accurate estimate of the noise reading possible.

A Times Facsimile fork model *FK2B* was used. The relative transmission versus frequency characteristics are shown in Fig. 2. The fork used was resonant at 1,600 cps with an effective bandwidth slightly less than 1 cps. The resonant frequency was found to depend only slightly on signal amplitude and remained stable to a few parts per million. It may be seen from Fig. 2 that the maximum loss is approximately 40 db which, by itself, is insufficient for the proposed measurements.

The selectivity of the General Radio *736A* wave analyzer was used to supplement the fork. A plot of its selectivity is shown on Fig. 3. This curve shows a relatively flat maximum which may lead to a shift of the curve relative to the fork. Tests showed that an allowance of ±05. cycles was sufficient to provide for mistuning and drift. Fig. 4 gives the computed over-all selectivity curves for the extremes of ±0.5 cycles mistuning. Compared with these curves are the results of several calibration runs made during the course of the tests. The comparison indicates that the calibration is stable and will give reliable measurements in the range of interest. Further, graphical integration of the curve gives an effective bandwidth of 0.7 cps for the combination.

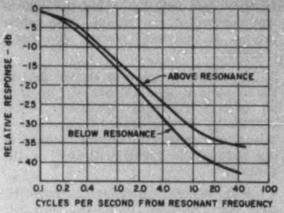

Fig. 2. Relative response versus frequency of tuning fork near resonance

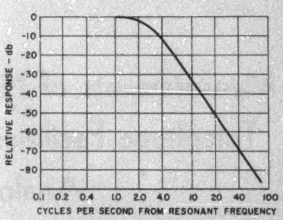

Fig. 3. Relative response versus frequency of wave analyzer

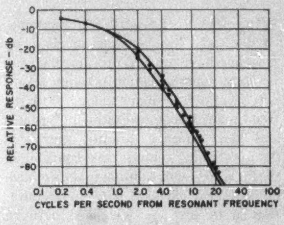

Fig. 4. Over-all response of narrow-band noise detector

The charge time constant of the integrator in Fig. 1 is approximately 10 seconds while the discharge time constant is 500 seconds. Successive readings taken on a white-noise source were reproducible within ±0.5 db when the sample time was 1.5 minutes. This period was used in the measurements.

To calibrate the instrument, a signal consisting of a tone mixed with white noise was applied to the input terminals. The noise was 3-kc band-limited white noise and the signal-to-noise ratio was 20 db. On the basis of an effective bandwidth of 0.7 cps the readings should approach an asymptote 56.3 db below the

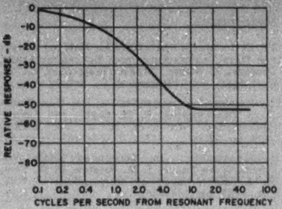

Fig. 5. White-noise calibration of system

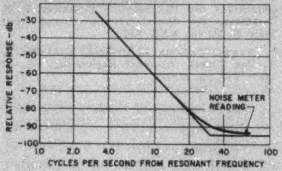

Fig. 6. Noise measurement of cable facility

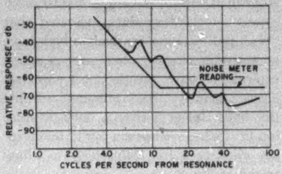

Fig. 7. Noise measurement of type O carrier telephone system

tone. The result of this measurement is plotted on Fig. 5. The final asymptote is 53.5 db below the tone. The slightly higher reading is reasonable in view of the peak reading nature of the indicating circuit.

NARROW-BAND NOISE MEASUREMENTS

The narrow-band noise measurements were made on a looped basis, that is, both the transmitting and receiving ends of the circuit were in the same laboratory. Precautions were taken to insure negligible direct coupling between generator and detector. The amplitude of the received signal was brought to a standard amplitude by a quality program amplifier before applying it to the detector. This was done to reduce to a minimum the possible effects of changing signal level on the selectivity of the fork. Tests indicated that no detectable noise or distortion was introduced by the amplifier. The frequency of the test oscillator was monitored and held accurate to better than ±0.2 cycle. The level of the tone applied was adjusted to be 0 db referred to 1 milliwatt at a 0 transmission level point. This is a standard testing level.

To serve as a reference, the results of a noise measurement on a high-grade cable circuit are shown on Fig. 6. This facility gave telewriting performance which was in excellent agreement with the prediction based on *2B* noise meter measurements. This is supported by the curve which closely follows the selectivity curve and approaches the *2B* reading asymptotically. In this case, as well as the others which follow, the reading of the *2B* noise meter was adjusted in accordance with its effective bandwidth to permit comparison with the measuring equipment described in this paper.

The measurements made over a type *O* carrier system are shown on Fig. 7. There appears to be definite evidence of tones superimposed on noise lying in a band extending approximately 15 cycles from the signal. The level of the noise in this band is approximately 20 db higher than the level of noise further removed in frequency from the signal.

A similar picture is obtained from measurements over a type *ON* carrier system as shown on Fig. 8. Here the band of noise extends approximately 30 cycles from the signal.

The results of measurements over a type *N* carrier system are shown on Fig. 9. There is evidence of narrow-band noise extending approximately 30 cycles from the tone. However, its magnitude is not sufficient to explain the telewriter failure. Measurements made over other *O*, *ON*, and *N* systems led to similar results.

Analysis of Results

Detailed examination of these carrier systems leads to several possible explanations of the foregoing results. The type *O* and *ON* carrier systems are single sideband systems employing twin-channel operation,[6] that is, a separate voice channel is derived from each sideband of a channel carrier. The channel carriers are transmitted at depressed levels. At the receiving end the carriers are selected by means of a narrow filter (±40 cycles for type *O* and ±100 cycles for type *ON*), amplified and applied to the demodulator at the proper level to assure stabilized demodulation.

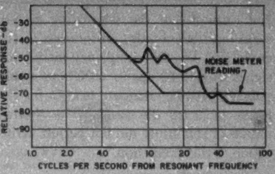

Fig. 8. Noise measurement of type ON carrier telephone system

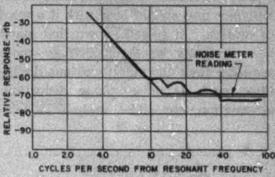

Fig. 9. Noise measurement of type N carrier telephone system

Noise in the band of the pick-off filter consists mainly of carriers of other systems or the carrier shifted slightly in frequency due to inaccuracies of the 304-kc repeater oscillator (in *ON*) which have been superimposed upon the wanted carrier through tertiary crosstalk paths. These unwanted carriers are normally of the order of 40 db below the wanted carrier and so have little effect on the transmission of speech. However, any single frequency transmitted over an *O* or *ON* channel is received with a band of modulation lying on either side of it. Whether this appears as a few discrete frequencies or a band of noise depends on the number of paralleling systems and the number of repeaters (in *ON*). The width of the band of modulation is determined by the differences between the various oscillator crystals involved with an upper limit imposed by the carrier pick-off filter. The foregoing explanation is consistent with the results of the noise measurements over *O* and *ON*. Additional experiments would be required for a definite confirmation.

It may be noted that the level of the narrow-band noise in the type *N* system is approximately 10 db lower than in type *O* and *ON*. This would be expected if the noise were caused by the same mechanism as in *O* and *ON*, since in *N* a higher channel carrier level is employed. However, the magnitude of the noise is insufficient to account for the telewriting performance encountered. Thus, the results of the measurements on *N* carrier indicate that another noise source may be present which was not detected by this method of measurement.

In many cases of analog-data transmission it is possible to overcome the effect of these interferences by increasing the bandwidth used to transmit the signal.

For example, in the telewriting system mentioned previously, an increase in the deviation of the frequency-modulated signal from ±52 cps to ±200 cps would possibly provide adequate margin for the types of noise discussed. The limited nature of this study did not permit verification of this prediction.

Conclusion

The successful use of voice facilities for nonvoice uses should bear with it a word of caution. It is well known that many data systems are considerably more sensitive than the ear to various distortions, such as noise, phase distortion, attenuation, etc. The study of a telewriting system pointed out the need for a technique capable of measuring a narrow band of noise close by in frequency and many db below a signal. Such measurements revealed the presence of a narrow band of interference on either side of a tone transmitted over a few widely used carrier telephone systems. A solution to the problem of transmitting analog signals over these systems is suggested. The design of new analog-data systems for use on voice facilities must take into consideration these small transmission anomalies which are generally of no concern. It is believed that the results of the work just described should prove helpful when considering proposals for sending analog data over voice facilities.

A Comparison of Mouth-to-Mouth and Manual Artificial Respiration Techniques

ARCHER S. GORDON
NONMEMBER AIEE

CHARLES W. FRYE
NONMEMBER AIEE

CHEMICAL, industrial, and mechanical progress have increased the incidence of cases requiring artificial respiration in industrial, military, and civilian spheres. The danger from electricity is a potent factor in all of these situations.

Recognition of this problem has created a profound interest in resuscitation and has resulted in careful experimental studies of both manual and mechanical methods of artificial respiration. These studies have clearly defined the manual and mechanical techniques which are physiologically superior, and practical application has substantiated these findings.

Throughout this work there has been a growing realization that manual resuscitation and mechanical resuscitation are not distinct entities competing for control of the victim's airway. They are separate but integral parts of the same picture. In the final analysis, there is no conflict between manual artificial respiration and mechanical resuscitation. When available, properly designed and competently employed mechanical resuscitators are easier to use (especially for prolonged periods of time), provide oxygen or air-oxygen mixtures, and leave the operator's hands free for maintaining an unobstructed airway. Such devices should be brought into operation as soon as practical. However, the use of mechanical resuscitators must remain always a secondary consideration. In resuscitation emergencies, time is of the essence, seconds count, and the breach between respiratory failure and the use of mechanical devices must always be filled by the use of a manual technique (Fig. 1). However, it is not sufficient merely to satisfy this time requirement by immediately beginning manual artificial respiration. It is equally important: 1. to use the best manual method; 2. to perform the method correctly and adequately; and 3. to maintain an unobstructed airway for unimpeded ventilation.

Background for Current Studies

Several years ago a series of carefully controlled human studies was carried out to evaluate the various factors concerned with manual artificial respiration. These tests were performed on warm, nonrigid corpses,[1] anesthetized normal adult male volunteers whose breathing was stopped with drugs,[2] surgical patients,[3] and patients whose breathing stopped as a result of various disease processes.[4] Ventilatory data indicated that "push-pull" manual methods, which have an active inspiratory phase and an active expiratory phase, are the most effective. These include: back-pressure arm-lift (modified Holger Nielsen); back-pressure hip-lift (Schafer-Emerson-Ivy); and arm-lift chest-pressure (Silvester), as illustrated in Fig. 2.

Circulatory studies[5] also were performed and revealed that all of these methods maintained near-normal amounts of oxygen in the blood. Air-flow studies[6] indicated that a performance rate of approximately 12 complete cycles per minute provided optimum ventilation. Performance and fatigue tests[7–10] showed the back-pressure hip-lift method to be more tiring and less accurately performed than back-pressure arm-lift. Airway obstruction, it was noted, occurred in 50% of the cases using the Silvester method due to the supine position.[1]

Vol.
Pt. 1
1959

On the basis of these studies, the National Research Council recommended in 1951 that the back-pressure arm-lift method was the preferred technique for general use. The other two push-pull methods were recommended as useful where particular circumstances demanded their application.[11] This decision was accepted by the American Red Cross, American Medical Association, Department of Defense, U.S. Public Health Service, Federal Civil Defense Administration, and most other national and federal agencies, utilities, and organizations concerned with resuscitation.

Pole-Top Method

It was suggested subsequently that the push-pull principle be applied to pole-top resuscitation. Human studies were performed[12] and revealed the ventilatory superiority of this method (Fig. 3) over the standard pole-top technique.[13,14] On a practical basis, push-pull pole-top resuscitation has been found effective. However, it has been criticized in some instances because the situation of the victim in relation to crossbars, wires, etc., precluded proper and adequate performance of the maneuvers.

A worthwhile recommendation for such situations (suggested in a personal communication from T. M. C. Martin) would be to have mechanical resuscitators equipped with extension hoses from the tanked gases to the face mask and all possible operating controls at, or near, the mask. This would allow rapid, adequate, and easy application on the pole. The mechanical resuscitation could be continued while the victim was being lowered. This practical adaptation of mechanical resuscitation deserves further investigation and development. Useful as such equipment might be, however, the urgency still remains for immediate ventilation of the victim. Accordingly, until such a mechanical device can be taken up the pole to the victim, some form of manual artificial respiration should be applied. Where the situation allows use of push-pull maneuvers these are preferable. If not feasible, standard pole-top resuscitation should be used.

Evaluation of Mouth-to-Mouth Method

In October 1955, Rickard[15] suggested that infants and small children could best be resuscitated manually by rocking them alternately into a 45-degree head-down and 45-degree feet-down position on the forearm of the rescuer. This modified Eve method[16] included the use of a digital airway at all times provided by the operator's middle finger which was inserted into the child's mouth to keep the jaw and tongue from obstructing the airway. The importance of maintaining a clear airway was stressed.

Concurrently, in the Armed Forces, Johns and Cooper,[17–18] and Elam and Brown, and associates,[19–21] were studying mask-to-mask insufflation for personnel requiring resuscitation in an atmosphere contaminated with nerve gases. They also studied mouth-to-mask insufflation

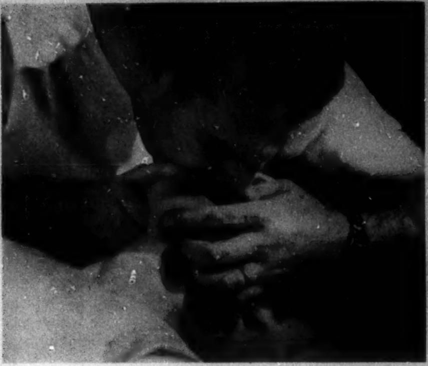

Fig. 4. Adult mouth-to-mouth insufflation

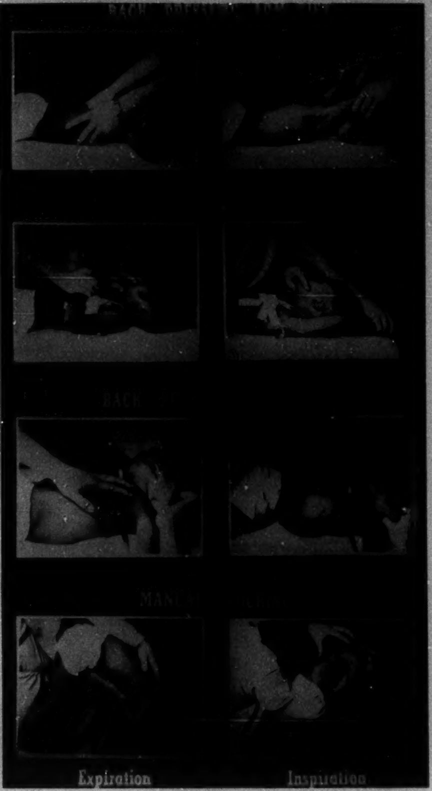
Fig. 5 (right). Push-pull manual artificial respiration techniques for infants and small children

Fig. 6 (below). Mouth-to-mouth insufflation technique for infants and small children



for use on hospital patients or in other situations where face masks were immediately available. These studies stressed ease of application, even for prolonged periods of time, maintenance of normal oxygen and carbon-dioxide levels in the blood, and the superiority of this technique for maintaining an unobstructed airway.

Since all of these recent studies have stressed the factor of airway patency, the authors undertook to evaluate this factor with the manual push-pull methods and direct mouth-to-mouth insufflation on a series of nonbreathing adults and on a similar series of infants and small children. The manual-rocking method was also included in the survey on children.

Methods

Controlled, comparative studies were performed on eight anesthetized normal adult males whose breathing was completely stopped by means of drugs. Ventilatory volumes were measured during the application of mouth-to-mouth insufflation, Silvester, back-pressure arm-lift, and back-pressure hip-lift methods of resuscitation. These were performed first with a cuffed endotracheal tube in the airway. This indicated the volumes achieved under ideal circumstances with the patency of the airway assured. The methods were then repeated without the endotracheal tube. Instead, a rubber mouthpiece was fitted between the teeth and lips and a clip was used to close off the nose. The mouthpiece was then connected to the spirometer to measure ventilatory volume. This leaves the tongue and jaw free to assume their normal position during actual resuscitation maneuvers and provides a measure of the airway obstruction occurring with each of the methods. The manual methods were performed as illustrated in Fig. 1, and mouth-to-mouth insufflation as shown in Fig. 4.

The infant studies were carried out on patients ranging in age from 5 to 36 months. They were performed prior to elective surgical procedures in a manner similar to the adult tests. The manual methods were applied both with and without a digital airway wherever pos-

Table I. Mean Pulmonary Ventilation During Artificial Respiration on Eight Apneic Normal Adult Male Subjects

Methods	Cuffed Endotracheal Tube: Cubic Centimeter per Respiratory Cycle	Mouthpiece and Noseclip: Cubic Centimeter per Respiratory Cycle	Mouthpiece and Noseclip: % of Cases Actually Ventilated*
Normal resting tidal volume	640		
Mouth-to-mouth	980	890	100%
Silvester	820	450	50%
Back-pressure arm-lift	950	580	75%
Back-pressure hip-lift	1090	650	75%

* In similar previous studies,[1] using mouthpiece and noseclip on eight warm, nonrigid corpses, the per cent of cases actually ventilated was: Silvester, 50%; back-pressure arm-lift, 100%; back-pressure hip-lift, 100%.

sible. Since the back-pressure arm-lift method requires the use of two hands, it was impossible for a single operator to insert a digital airway with this technique. The push-pull manual methods and manual rocking are illustrated in Fig. 5, and mouth-to-mouth insufflation for infants in Fig. 6.

RESULTS

The ventilatory data from the adult studies are summarized in Table I. With an ideal airway provided by the cuffed endotracheal tube, all push-pull manual methods and mouth-to-mouth insufflation gave the same range of ventilation, and this was one quarter to three quarters more than the resting tidal volume. When the mouthpiece and noseclip were used, ventilation was reduced with all methods. However, mouth-to-mouth insufflation showed less than a 10% decrease, whereas the push-pull manual methods all resulted in approximately 40% to 50% less ventilation. This reduction is due to partial airway obstruction without the endotracheal tube. Of even greater importance is the observation that all cases were ventilated by mouth-to-mouth insufflation, whereas only 75% of them were ventilated by the back-pressure arm-lift and back-pressure hip-lift techniques, and only 50% with use of the supine Silvester method.

The data on infants and small children are itemized in Tables II and III. With the endotracheal tube providing an ideal airway, mouth-to-mouth insufflation always provided maximum pulmonary ventilation, usually two to three times the normal resting tidal volume. The manual push-pull techniques all provided the same range of ventilation and usually about one half to two thirds as much as the mouth-to-mouth method. All variations of manual rocking were significantly inferior and resulted in less ventilation than the resting tidal volume. When the mouthpiece and noseclip were used, mouth-to-mouth resuscitation essentially resulted in as much ventilation as with the endotracheal tube, and every case was ventilated. With the push-pull manual methods all cases were ventilated when a digital airway was used, although the volume was significantly less than with mouth-to-mouth resuscitation. When the digital airway was not used, only one half of the cases were ventilated. With the manual rocking techniques, only one half of the patients were ventilated

* Same cases as in Table 1.
† In each series, "(A) With" indicates the results obtained when the method was performed with the operator's finger in the mouth to keep the airway clear; "(B) Without" indicates the results without a finger in the airway; back-pressure arm-lift requires the operator to use both hands, therefore, all of these measurements were made without a finger in the airway; all manual rocking was performed with a finger in the airway.

even with a digital airway. This was attributed to flexion of the neck during rocking which frequently resulted in obstruction of the airway.

DISCUSSION

Direct mouth-to-mouth resuscitation has been recommended and practiced since Biblical days. But comparative, controlled tests have never been performed previously. They emphasize a number of important features of the technique.

With an assured ideal airway, mouth-to-mouth insufflation (at an optimum pressure of approximately 15 millimeters mercury) provides the same tidal ventilation as a well-performed push-pull manual method. However, when an endotracheal tube is not used, airway obstruction becomes a vital problem which can partially or completely nullify the resuscitation effects. Properly performed mouth-to-mouth insufflation is the only nonmechanical technique which provides optimal ventilation in all cases for both infants and adults. Carefully performed push-pull manual methods provide only partial or sometimes no ventilation, unless a second rescuer can devote himself to assuring the patency of the airway, or, for children, a digital airway is used.

There are other advantages to mouth-to-mouth insufflation. When the rescuer breathes into the victim's airway, he can immediately detect obstruction by feeling resistance to insufflation and by noting that the chest fails to rise and fall rhythmically with each breath. Since he is stationed at the victim's head, he easily can check the airway to relieve the obstruction. With none of the manual methods is the operator able to detect airway obstruction nor is he in a good position to relieve it.

If partial obstruction occurs and cannot be digitally relieved, the rescuer can increase his insufflation pressure in order to ventilate the lungs. This is not possible with the manual methods. He can also slow his rate of insufflation to bypass a partial obstruction. Additional pressure is also useful for ventilating the noncompliant lung, such as is found in cases associated with pulmonary edema. Such pressure increases cannot be accomplished with any manual method.

Elam's studies reveal the ease and effectiveness of mouth-to-mouth insufflation even for long periods of time. In addition, disproportions in size do not limit the small operator from performing mouth-to-mouth insufflation on a large victim as do the push-pull manual methods.

Inspired air contains 20 to 21% oxygen and a trace of carbon dioxide; expired air is approximately 16% oxygen and 4 to 5% carbon dioxide. This amount of oxygen is more than adequate for the body's needs, and this low concentration of carbon dioxide is not deleterious if sufficient pulmonary ventilation is achieved. Elam's studies[19-21] have shown conclusively that mouth-to-mouth insufflation can maintain normal amounts of oxygen and carbon dioxide in the victim's blood during long periods of application.

Mouth-to-mouth insufflation can be applied in many situations where the manual methods are seriously limited, such as for fractures or severe injuries of extremities and thorax, for burns, and for cases where the victims are in unusual positions or parts of their bodies are trapped. Whether it would be practical to attempt mouth-to-mouth ventilation of a pole-top victim is not known. There are times when it might be possible and preferable. Rather than advocate one or the other method, it would appear wiser to re-emphasize that some method must be started at once. The individual operators should be capable of performing the mouth-to-mouth technique as well as standard pole-top and push-pull pole-top maneuvers. Mouth-to-mouth and push-pull pole-top resuscitation give greater ventilation and should be used when possible. Otherwise standard pole-top resuscitation should be started and continued until the victim can be lowered to the ground or a mechanical resuscitator with an extension mask brought up to him on the pole.

RECOMMENDATIONS AND TECHNIQUE

As a result of these recent findings, the National Research Council and the American Red Cross have recommended that the preferable nonmechanical method of resuscitation for infants and small children is mouth-to-mouth insufflation. They also state that this method may be used for adults. Although the efficacy of the method has been recognized for adults, it is felt by some that the aesthetic aspects of performing mouth-to-mouth insufflation on near-dead, cyanotic, moist, etc., adult victims may deter rescuers from using it. In such cases, push-pull manual methods remain as an alternative. To overcome some of these aesthetic considerations, a clean piece of cloth or gauze may be interposed between the rescuer's and victim's mouths. However, this makes performance more difficult, somewhat increases the resistance to ventilation, and may not be readily available. Valuable time should not be lost in seeking or applying this adjunct.

The technique for performing mouth-to-mouth insufflation is essentially as illustrated in Figs. 4 and 6. For infants and small children, the rescuer should place the victim on his back and use the middle and/or ring fingers of both hands to lift the lower jaw from beneath and behind so that it juts out. This draws the base of the tongue forward and keeps the airway from obstructing. He then places his mouth over the child's mouth *and* nose, making a relatively leakproof seal, and breathes into the child's airway with a smooth, steady action until he observes the chest rise. This phase is continued until the rescuer feels the resistance of the victim's lungs. As he starts this action, he moves one of his hands to the child's stomach, between the navel and the ribs, and applies continuous, moderate pressure to prevent the stomach from becoming distended with air. The other hand is maintained in its position under the jaw to keep the airway clear. As soon as the lungs have been inflated, the rescuer removes his lips from the child's mouth and nose and allows the lungs to empty passively. The cycle is then repeated, keeping one hand behind and beneath the jaw, and the other pressing on the stomach at all times. This should be continued at a rate of about 20 per minute. After every 20 cycles, the operator should rest long enough to take one deep breath. If at any time he feels resistance to his breathing into the airway, or fails to see the chest rise and fall rhythmically, he should quickly lift the lower jaw again with both hands in order to keep the airway clear.

If the rescuer cannot ventilate the lungs of the victim, even after carefully holding the jaw forward as directed, the possibility of a foreign body in the airway should be entertained. The victim should be placed on the rescuer's forearm in a face-down head-down position with the middle finger of the rescuer's hand inserted into the airway to hold the tongue forward. He should then pat him firmly on the back to dislodge any foreign body. Mouth-to-mouth insufflation should then proceed as directed.

The method is essentially the same for adults, with the following exceptions. The rescuer breathes only into the mouth (or nose) of the victim. Both hands are usually required to keep the jaw elevated and it is not always possible to move one hand to the abdomen. The rate should be approximately 12 complete cycles per

Vol.
Pt. 1
195

minute, with the rescuer taking one deep breath between each 12 cycles. When the rescuer breathes into the victim's mouth, it is necessary for him to obstruct the nose with his two thumbs in order to prevent the escape of air.

Summary

1. With an ideal, unobstructed airway, mouth-to-mouth insufflation has been found to give as effective ventilation as push-pull manual methods of artificial respiration.

2. When an ideal airway is not assured, such as under practical resuscitation conditions, the mouth-to-mouth method is the only nonmechanical technique which assures a patent airway.

3. Even the well-performed push-pull manual methods frequently result in partial or complete obstruction of the airway.

4. Mouth-to-mouth insufflation is the preferred nonmechanical method of resuscitation for infants and small children. It should also be used for adults if the rescuer can overlook the aesthetic aspects of the situation. Push-pull manual methods are a second choice.

5. For pole-top resuscitation, some method of artificial respiration must be started at once. Mouth-to-mouth insufflation and push-pull pole-top resuscitation give the best ventilation and should be used if practical. If not, standard pole-top resuscitation should be employed until a mechanical resuscitator with mask extension can be taken up the pole, or the victim can be lowered to the ground.

Thermal Life of Enameled Magnet Wire

AIEE COMMITTEE REPORT

IN THE SUMMER of 1953, a Working Group on Thermal Stability of Insulating Materials was organized under the sponsorship of the AIEE Subcommittee on Electrical Insulation (formerly the Dielectrics Committee) of the Basic Sciences Committee. In January 1954 a task force on the Evaluation of the Thermal Stability of Enameled Magnet Wire was appointed and it was given the responsibility of developing a test procedure.

A suggested test method presented at the 1955 AIEE Winter General Meeting was adopted for further study and a cooperative test program was started.[1] This method consisted of heat aging National Electrical Manufacturers Association electric strength test samples and subjecting them to a predetermined test voltage applied periodically during the aging. The end point was determined by the breakdown of the wire specimens.

As a result of this program, a report and a proposed test procedure were presented at the AIEE Fall General Meeting in October 1954. In October 1955, AIEE Publication no. *57* was issued by the Institute.[2] This test procedure is the responsibility of the Working Group on Enameled Magnet Wire, Subcommittee on Thermal Evaluation, Electrical Insulation Committee.

Temperature Classification

The 1957 revision of AIEE Publication no. *1* establishes the concept that temperature ratings of insulating materials and systems shall be based upon "experience or accepted tests."

Publication no. *1* further states that the classification of insulating materials involves two steps: 1. preparing test procedures, and 2. establishing minimum thermal life values based upon results of aging tests on known materials.

Although AIEE no. *1* specifies that

Paper 58-1205, recommended by the AIEE Electrical Insulation Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Pittsburgh, Pa., October 26–31, 1958, and represented at the Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted June 27, 1958; made available for printing August 18, 1958.

The members of the Working Group on Enameled Magnet Wire, Subcommittee on Thermal Evaluation of the AIEE Electrical Insulation Committee are J. F. Dexter, *chairman*, Ralph Hall, K. N. Mathes, E. L. Brancato, H. L. Saums, F. A. Sattler, D. L. McClenahan, J. M. Keller, R. B. Young, T. J. Gair, F. E. Dresner, W. W. Wareham, C. E. Logston, Edward Lavin, K. Alexander.

technical committees will determine the minimum thermal life values for new materials, temperature classification involves commercial considerations in addition to purely technical questions. In trying to develop a procedure for classifying the temperature ratings of enameled magnet wire, it became obvious that these commercial matters could not be resolved by the AIEE Working Group. However, it is important that some practical procedure be worked out so that the temperature rating of each new insulating material can be determined.

As a step toward the preparation of these specifications, thermal-aging data must be available. For the past several years, the Electrical Insulation Committee has sponsored the presentation of technical papers on magnet-wire thermal-stability studies. During this time, members of the AIEE Working Group have obtained data on the many different types of enameled wire. These data may be used to establish base lines against which the life of new enamels be compared.

Test Procedure

Data given in this report have been obtained according to the methods outlined in AIEE no. *57* test procedure. Deviations from no. *57* are noted where they are known to exist.

Data are given on unvarnished and varnished test specimens. The general chemical classification of the insulating varnishes used to coat the specimens is given when available, but formulations within a class can vary widely. In many cases, the wire size was not reported. However, most of these data were obtained on no. *18* Awg (American Wire Gauge) and no. *20* Awg copper wire.

Types of Enameled Magnet Wire

In reporting thermal life data, commercial enamels are classified according to their chemical composition. Generally, each type of enamel has a thermal life-temperature characteristic typical of its chemical composition, but variations in life can be expected for different formulations within a chemical type.

The following chemical classifications have been selected arbitrarily in presenting data:

Polyvinyl formal
Epoxy
Epoxide-polyester
Polyester
Polyester-polyamide
Polyamide

Statistical Analysis of Thermal Life Data

Thermal life values for each type of enamel are presented in tabular form. Each value given in the tables is the average life of ten or more magnet wire specimens. Life values for varnished and unvarnished specimens are given. The equation for the regression line for each enamel was determined according to the procedure given in AIEE no. *1(F)*.

In Table I, a detailed summary of the statistical calculations is given. These data may be useful to those wishing to reproduce the graphs or to compare thermal life values of different enamels.

In analyzing the data obtained on varnished specimens, the variations in life caused by different varnishes must be considered. Since different varnishes may result in different life–temperature relationships, the regression line is of little significance. Therefore, with two exceptions, graphs showing the life as a function of aging temperature are given only for unvarnished specimens.

As a result of the AIEE test programs, there were considerable data available for polyvinyl formal coated with a phenolic-alkyd varnish and for a silicone modified polyester enamel coated with a silicone varnish. In these cases a graph is included showing the life temperature characteristic of these varnished specimens.

Thermal Life of Enameled Magnet Wire

Polyvinyl Formal Enameled Wire. In Table II, thermal life values are given for unvarnished specimens of copper wire enameled with commercial polyvinyl formal enamels. Thermal life values obtained on varnished specimens are given in Table III. Most of the data on varnished specimens were obtained with modified alkyd varnish. However, the type of varnish used may affect significantly the thermal life. For example, in Table III the thermal life values reported by laboratory *E* show the difference between specimens dipped in polyester varnish and in phenolic varnish.

The equation for the regression line and the 95% confidence limits on the estimated life at 105 C (degrees centigrade) for unvarnished specimens are given in Table II. The range of 10,954 to 20,571 hours for 95% confidence in the averge life at 105 C is narrow, considering that these data were obtained over several years on different commercial enamels by nine laboratories. It is doubtful that further testing of this type of enamel will significantly improve the estimated life at 105 C. Data given in Tables II and III are shown graphically in Figs. 1 and 2.

This enamel has been used successfully for many years in electric equipment designed for class *A* temperature rise. Therefore, it is logical to select polyvinyl formal enamel as the "accepted material," and its thermal life taken as a base for comparing the relative life of new enamels.

Epoxy Enameled Wire. Thermal life values for unvarnished and varnished specimens of epoxy enameled wire are given in Tables IV and V. In Fig. 3, the thermal life–temperature characteristic of unvarnished specimens is shown.

Epoxy-Polyester Enameled Wire. The thermal life values for unvarnished and varnished specimens of a polyester modified epoxide wire enamel are given in Tables VI and VII. The life as a function of temperature for this enamel is shown in Fig. 4.

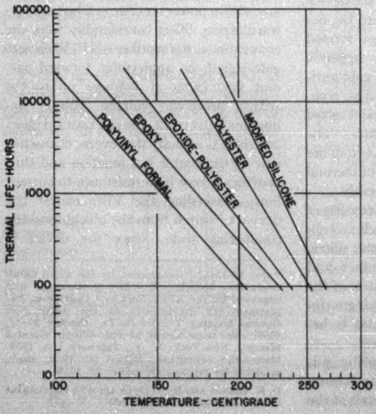

Fig. 11. Relative thermal life of enameled magnet wire, unvarnished specimens

polyester type enameled magnet wire are given in Tables VIII and IX. In Fig. 5 the life of the unvarnished enameled wire specimens are shown.

Polyamide Enameled Wire. Data on the thermal life of one polyamide type enamel are given in Tables X and XI. These data are shown graphically in Fig. 6.

Acrylic Enameled Wire. Thermal life values for acrylic enamels are given in Tables XII and XIII. An indication of the relative thermal life for unvarnished specimens is shown in Fig. 7.

Polyester-Polyamide Enameled Wire. Aging data on a polyester-polyamide-type enamel are given in Tables XIV and XV.

Polyurethane Enameled Wire. Thermal life values for unvarnished and varnished specimens of polyurethane enamels are given in Tables XVI and XVII. Life-temperature characteristics are shown in Fig. 8.

It is apparent in Fig. 8 that the life values for unvarnished specimens do not define a straight line. This fact has been reported by several investigators. Furthermore, the irregularity was noted in the statistical analysis and it was indicated by a low value for the coefficient of multiple correlation. This illustrates one of the reasons for determining thermal life values over wide temperature ranges recommended by this test method if the aging temperatures are below the transition temperature.

Silicone Modified Polyester Enameled Wire. Thermal life values obtained by the Working Group on unvarnished specimens of silicone modified enamels are listed in Table XVIII. Data on varnished specimens are given in Table XIX. The thermal life values for unvarnished specimens are shown in Fig. 9. Two different silicone modified enamels are reported. One enamel that had a relatively poor thermal life when tested without varnish is no longer available commercially.

The difference in thermal life between the two silicone modified enamels is not evident when silicone varnished specimens are tested. The average life of silicone varnished specimens is shown in Fig. 10. Since many sets of samples aging at 200 C are still under test, a life at this temperature cannot be established. Therefore, life values already obtained at 200 C are not included in calculating the average life characteristic.

It is evident that the life values at 200 C do not fall on the line defined by data obtained at higher temperatures. Apparently two deteriorating reactions are taking place. Loss of adhesion of the enamel to copper and chemical reactions between the enamel and copper at high temperatures could be explanations for these phenomena.

These data illustrate why it is so important to have long-time aging tests at temperatures approaching service values before estimating the temperature classification of materials.

Polytetrafluoroethylene Enameled Wire. Only one member of the Working Group has reported data on polytetrafluoroethylene enameled magnet wire. These data, given in Table XX, are included only to give an indication of the relative life that may be expected from this heat-stable coating.

It is also interesting to note the significant decrease in life when a 2.0-kv test voltage is used. Generally, the difference in thermal life obtained using different test voltages is not so pronounced.

Summary

Data from individual graphs are summarized in Fig. 11. These curves, comparing the relative thermal life characteristic for unvarnished specimens, indicate the range of thermal stability among the various types of enamels.

In most cases, more data are needed to establish thermal life characteristic with a greater degree of confidence. Especially needed are life values at lower aging temperatures However, more data will not change the relative positions of the thermal life lines shown in Fig. 11.

Since varnish influences the life of enameled magnet wire, the relative life of varnished specimens cannot always be compared. A study of varnished specimens is further complicated by the fact that a particular varnish may increase the life of one type of enamel and decrease the life of some other enamel. It is suggested that effects of varnish on the thermal life be determined by comparing the life of varnished and unvarnished specimens. In this way, an indication of the degree of increased or decreased life can be estimated.

Evidence given in Figs. 8 and 10 shows that the slope of the life–temperature line may not always be constant. Oxidation of the copper wire, chemical reactions between copper and the enamel, and varying chemical reaction rates may account for this phenomenon. While this phenomenon may occur only for some enamels or for tests conducted at very high temperatures, it does indicate that predictions of thermal life based upon short-time aging tests should be viewed with suspicion.

A Silicon-Controlled Rectifier

I—Characteristics and Ratings

D. K. BISSON
ASSOCIATE MEMBER AIEE

R. F. DYER
NONMEMBER AIEE

THE NAME silicon-controlled rectifier has been given to a new 3-terminal semiconductor device which has electrical characteristics similar to a thyratron. This device has been developed by the Semiconductor Products Department of the General Electric Company and has been given the developmental designation *ZJ-39A*. Its characteristics are made possible through the use of a *p-n-p-n* junction configuration. It is capable of handling load currents up to 16 amperes average at peak voltages up to 300 volts. Its fast switching action, small size, and relatively high-current ratings make this new device adaptable to a great many applications. Its characteristics and ratings, which are of utmost importance to the circuit designer, are the subject of this discussion.

Construction

Fig. 1 shows the physical appearance and relative size of the silicon-controlled rectifier. A stud-mounted design has been chosen to facilitate mounting to a heat sink and the top terminal lends itself to either bolt-on or soldered-lead connections.

The internal construction of the device is shown in Fig. 2. The heart of the device is the *p-n-p* silicon pellet formed by diffusion techniques. The upper *n* region is made by alloying the gold antimony into the *p*-type silicon. This completes the *p-n-p-n* structure and gives the device its basic characteristics. The molybdenum disks on top and bottom are included to minimize the effects of thermal expansion on the complete assembly.

The gate or control electrode consists of the small aluminum wire which is connected to the top *p* layer of the silicon pellet. This is an ohmic contact and not a rectifying junction. Control of the device is accomplished by applying a signal to the top *p-n* junction; that is, between the gate and cathode leads.

The subassembly as shown in Fig. 2 is then housed by welding to the bottom molybdenum disk. When the ends of the terminal tubulations have also been welded, a hermetically sealed unit exists. This housed subassembly is then carefully soldered to the copper stud, thus providing a low thermal resistance from the junctions of the device to the external heat sink.

Electrical Characteristics

Basic Electrical Characteristics

Fig. 3 shows the basic voltage-current (E-I) characteristics of the controlled rectifier. The reverse region is typical of any silicon power rectifier cell but the forward region differs considerably from the conventional *p-n* rectifier cell. With zero gate signal, no appreciable forward current flow exists at voltages up to the critical breakover voltage (VBO). Below this VBO point, the cell forward characteristic is actually the reverse characteristic of the center *p-n* junction and thus provides a very high resistance to current flow. Exceeding the VBO causes the device to switch from the blocking to the conducting state. Once the device is

Fig. 1. General Electric ZJ-39A controlled rectifier

in the conducting state the forward characteristic is typical of any medium-power silicon rectifier exhibiting low dynamic resistance to current flow.

The foregoing explanation of the forward characteristic was based on 2-terminal operation of the device. When operated under these conditions the device will return to the blocking or nonconducting state if the load current is reduced below the value designated as the holding current I_h on Fig. 3. When 3-terminal operation is employed, and sufficient gate current is fed into the gate terminal, the device will then exhibit a forward characteristic similar to that of a *p-n* junction; that is, the forward blocking region will disappear completely.

The theory of operation of the device is beyond the scope of this paper. However, papers have been presented which describe the theory of operation of *p-n-p-n* switches in detail.[1,2]

REVERSE E-I CHARACTERISTICS

Typical reverse characteristics for 125 C (degrees centigrade) junction temperature are shown in Fig. 4. The curves shown are for the various voltage grades to which the cell is now manufactured. The rectifiers are segregated into these several classifications according to their reverse breakdown voltage and the magnitude of the reverse-leakage current at a particular reverse voltage. This PIV (peak inverse voltage) rating procedure is identical to that used on many other types of silicon power rectifiers.

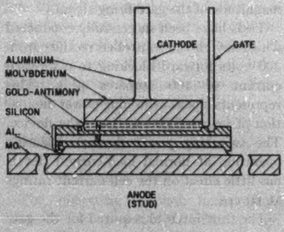

Fig. 2. Internal construction

Data for reverse characteristics such as shown in Fig. 4 have been generated by laboratory measurement since it is difficult to predict mathematically what the reverse leakage currents will be. This is particularly true for the lower voltage grades.

At junction temperatures in the vicinity of the rated junction temperature (125 C) the reverse current at a given voltage increases exponentially with increasing temperature and can be approximated by the equation:

$$I_{RT_1} = I_{RT_2} e^{r(T_1 - T_2)} \qquad (1)$$

where

$T_2 - T_1$ = the temperature rise being considered

I_{RT_1} = the reverse current at T_1

I_{RT_2} = the reverse current at T_2

r = constant of temperature variation -0.06 per C

Equation 1 gives reasonably realistic results when used for the higher voltage grade cells over the temperature range of 125 C ± 50 C. For the lower voltage grades or for lower temperatures the reverse current varies considerably less with temperature than would be predicted by the foregoing equation. This effect is primarily caused by a relatively large surface leakage component of total reverse current which varies only slightly with temperature. The variation of reverse current with temperature is of particular importance in the rating of the device as will be discussed later.

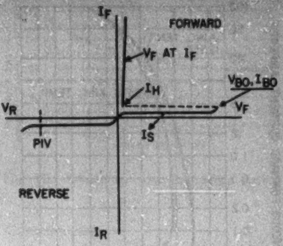

Fig. 3. Basic electrical characteristics

FORWARD E-I CHARACTERISTICS

As previously discussed, the forward E-I characteristics of the controlled rectifier represent two distinct states; the blocking or nonconducting state and the conducting or low-impedance state. Therefore it is more convenient to discuss the characteristics of each state separately.

The forward blocking characteristic is actually the reverse characteristic of the center *p-n* junction and therefore behaves in a similar manner. By simply relabeling the axis on Fig. 4 to read "instantaneous forward voltage" and "instantaneous forward current," the curves become typical for the forward blocking characteristics for the several voltage grades shown. The variation in the magnitude of forward leakage current with temperature is identical to that of the reverse characteristic.

There is one important difference between the reverse characteristic and the forward blocking characteristic of the controlled rectifier. If the maximum allowable PIV rating of the device is sufficiently exceeded, the device will eventually break down and will be destroyed by the avalanche-type currents

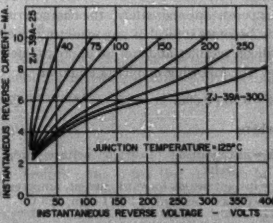

Fig. 4. Typical reverse characteristics

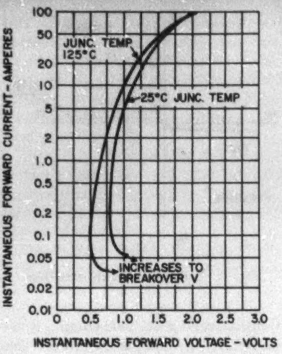

Fig. 5. Typical forward characteristics; conducting state

that would result. In contrast to this, exceeding the VBO of the forward characteristic is nondestructive in nature and will only cause the device to switch from the blocking to the conducting state.

The effects of temperature on the critical value of VBO are of interest. Not all cells follow the same pattern; that is, the majority of present production cells show a considerable decrease in VBO as the temperature is increased, but for others there is little change. Cells are classified according to the lowest value of VBO encountered over the operating temperature range and consequently the cell's VBO rating will apply over the entire operating temperature range.

The forward E-I relationships for the conducting state are shown in Fig. 5. At currents below approximately 100 milliamperes, the forward voltage drop actually increases slightly as the current decreases. This action represents the beginning of the transition between the conducting and blocking states. When the current is decreased below the critical current I_h required to maintain conduction, the device will cease conducting completely and return to the blocking state. At currents above 100 milliamperes (approximately) the characteristic becomes typical of any medium-power silicon rectifier and can be approximated by the following empirical equation:

$$V=0.78+0.0957 \ln i+iR \qquad (2)$$

where

V = instantaneous forward voltage drop, volts
i = instantaneous forward current, amperes
R = device constant of 0.011 ohm, 125 C

Evaluation of the constants is easily made from laboratory data. Equation 2 gives values of forward voltage drop which agree very well with measured values over the operating current range and therefore provides a convenient tool for calculating power generation curves.

The resistance in the last term of the equation has a positive temperature dependence in contrast to a negative temperature dependence for the second term. This causes the curves in Fig. 5 to cross over as shown.

FIRING CHARACTERISTICS

Since firing must be accomplished over a wide temperature range and for a considerable spread in firing requirements from unit to unit, a simple scheme had to be devised to present the information necessary for the design of firing circuits. This effort resulted in the firing characteristic shown in Fig. 6, where the complete range of cell-firing requirements are depicted by means of the shaded area. The nonlinear boundaries of the shaded area represent the maximum and minimum gate E-I characteristics that exist. These E-I characteristics are actually the forward diode characteristics of the top *p-n* junction, the junction between the gate and cathode leads of the cell. Factory testing is designed to assure that all cells will fire within the shaded area. The curve also places maximum allowable gate voltage and current limits of the cells. The maximum limits are primarily dependent on the very small internal gate lead used in the construction of the device. Load lines may be drawn, as are commonly used to depict ignitor firing requirements for ignitrons, which give impedance information necessary for the design of satisfactory firing circuits.

The reverse E-I characteristic of the gate diode (not illustrated) has not been designed to offer high resistance to current flow and consequently a diode in series with the gate is recommended to limit reverse gate current in applications where such conditions exist.

Firing requirements decrease only slightly with increasing anode to cathode voltage over the rated operating voltage range of the device. Cells will operate at applied anode to cathode voltages down to a few volts.

SWITCHING SPEEDS

The time to switch the controlled rectifier from the blocking to conducting state is approximately 1 μsec (microsecond) for typical cells and approximately 5 μsec for the slowest cells. This time includes a short delay time as well as the actual switching time. The switching action is depicted in Fig. 7. The delay time is approximately 0.5–1.0 μsec and is an inherent characteristic of the device. It can be minimized by proper control of the pulse width and magnitude of the gate-firing signal.

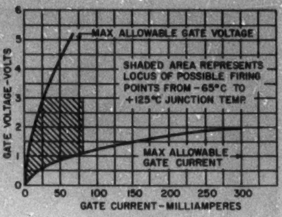

Fig. 6. Firing characteristics

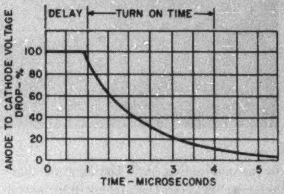

Fig. 7. Typical turn-on time

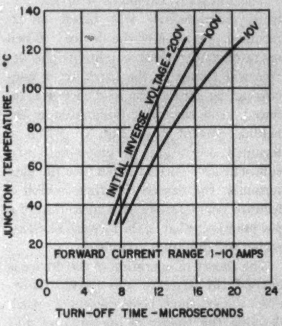

Fig. 8. Typical turn-off time

Tests have been successfully conducted which switch the controlled rectifier from 300 volts forward blocking to a forward current of 100 amperes peak. This represents a peak switching power dissipation of nearly 7,500 watts in the device. The switching power dissipated during operation at normal load-current levels has little effect on the cell-current ratings at 60 cps.

The time interval required for the gate to regain control after a forward current

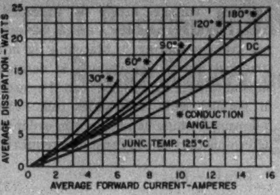

Fig. 9. Forward power dissipation

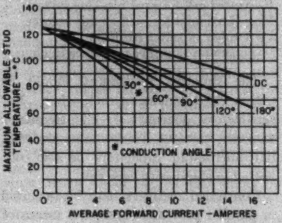

Fig. 10. Maximum allowable stud temperature

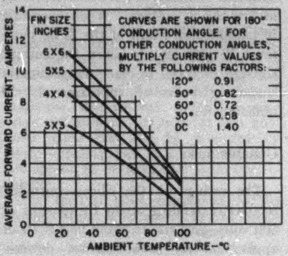

Fig. 11. Required fin size

is interrupted is defined as the turn-off time. The time to turn the device off is somewhat longer than is necessary for turn-on. Fig. 8 shows the relationships between turn-off time, junction temperature, and inverse voltage before turn-off for a typical unit. Forward current before turn-off has not been included as a variable because over the range of 1–10 amperes, for which data were taken, it affects the turn-off time only slightly. Increased forward current causes a slight increase in turn-off time.

Ratings

JUNCTION TEMPERATURE

The operating junction temperature range is −65 to +125 C. The storage temperature range is −65 to +150 C. A low temperature limit is required primarily in order to limit stress in the silicon crystal to safe values. This stress is due to bimetallic bending as the temperature is reduced below the freezing point of the materials used in fabricating the assembly. The upper operating temperature limit was imposed because of the temperature dependence of VBO, the maximum forward blocking voltage that can be withstood. The storage temperature limit of 150 C was selected to achieve maximum reliability and stability of characteristics with time.

THERMAL IMPEDANCE

The internal thermal impedance of the rectifier is defined as degrees centigrade per watt temperature rise of the junction above the cooling stud. The steady state value is 2 C/watt. Transiently, the thermal impedance appears smaller because of thermal storage. Because of the small thermal mass of the silicon pellet, substantial temperature fluctuations appear within a cycle when the supply frequency is 60 cycles. Because of this fluctuation, the rating curves are based on a peak junction temperature of 125 C for 60-cycle circuits. Since there are three junctions in the rectifier, a composite temperature as indicated by the change in forward voltage drop with temperature is used as a means of defining junction temperature.

POWER LOSS

Forward conduction losses are the major source of junction heating. Other losses are forward and reverse blocking loss, gate and switching power losses. Fig. 9 gives conduction loss in watts as a function of average current in amperes for various conduction angles. These curves are based on a current waveform which is the remainder of a half-sine wave which results when delayed angle firing is used. The length of each curve represents the permissible range of current for that particular firing angle. The power curves are the integrated product of the current waveform equation and the forward drop equation; see equation 2.

The maximum allowable stud temperature is shown in Fig. 10 as a function of average current. Conduction, gate, and blocking losses are included and switching loss is neglected. This curve is calculated for an operating frequency of 60 cycles. It becomes conservative at higher frequencies because the junction temperature excursion within a cycle becomes less. At some higher frequency, the heating effect of switching power loss will overcome this advantage.

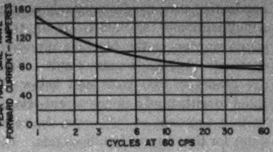

Fig. 12. Maximum allowable surge current

COOLING FINS

In order to maintain the junction temperature within the limits specified by Fig. 10, it is necessary to provide cooling for the stud, i.e., a cooling fin. Fig. 11 gives the required fin size as a function of average current and conduction angle for the following set of conditions:

Fin material	copper 1/16 inch thick
Surface emissivity	0.9 or higher
Air pressure	14.7 pounds/inch^2
Air velocity	free convection
Fin spacing	0.75 inch or more

For other conditions, the stud temperature, as measured by a thermocouple, can be used to determine if the cooling is adequate. For a given fin size, the allowable average current decreases with conduction angle since both blocking and conduction losses increase.

THERMAL STABILITY

The smallest fin size shown on Fig. 11 is 3 by 3 inches. For the cooling conditions given and with a junction temperature of 125 C and inverse voltage of 300 volts, this is the smallest fin size that provides a margin of safety against thermal runaway. Thermal runaway occurs when a critical value of reverse blocking power loss is exceeded. This value of power can be calculated from the following equation:

$$P_{R\,\max} = \frac{1}{Kr} \text{ watts} \qquad (3)$$

where

$P_{R\,\max}$ = maximum stable reverse-blocking loss
K = steady-state thermal resistance from junction to ambient in C/watt
$r = 0.06$

Reverse power loss may be decreased by operating at reduced voltages or junction temperatures.

TRANSIENTS

Voltage transients can be quite severe in circuits using controlled rectifiers because of the relatively fast switching speeds involved. If these transients appear across the rectifier in the forward direction, the rectifier may switch to the conducting state nondestructively causing a malfunction of the circuit. If the transients appear in the blocking direction, destructive breakdown may result. Voltage grades of 200 volts and below are rated to withstand a nonrecurrent reverse voltage transient of 50% over the rated value for times up to 5 milliseconds. For higher voltage cells, the transient-voltage rating is 100 volts above the rated PIV value. For repetitive transients, the peak value should not exceed the continuous PIV rating of the cell.

Forward current transients such as encountered during fault conditions can be withstood up to the values shown in Fig. 12. This curve relates the maximum allowable current peak of a 60-cycle half sine wave to the number of cycles. Under these conditions, the rectifier turns on at the beginning of the current pulse and the turn-on energy dissipated in the rectifier is low. If the rectifier is turned on into a fault after the voltage has built up across the rectifier in the forward direction, the energy dissipated in the rectifier during turn-on can be substantial. Because of this, the current cannot be allowed to exceed 100 amperes until after the turn-on interval has been completed.

When reverse voltage is applied to the rectifier immediately following forward conduction, the rectifier has a low reverse impedance until the stored carriers in the end junctions are swept out. This reverse recovery time varies with forward current, initial inverse voltage and circuit impedance but is normally less than 1 μsec. The maximum allowable current during this interval has not yet been established.

FREQUENCY RESPONSE

The maximum operating frequency for the controlled rectifier is influenced greatly by the circuit application and no single figure can be given. Operating frequency is limited by the turn-off time and switching power losses.

If the time between the end of forward current conduction and reapplication of forward blocking voltage is less than the turn-off time, the rectifier will not have regained control and the circuit will malfunction. The required turn-off time can be estimated from Fig. 8. For example, if a 3-phase bridge connected to an inductive load is phased back 90 degrees to obtain zero output voltage, only 90 electrical degrees are available for the rectifier to regain control. If the turn-off time were 20 μsec, the maximum operating frequency would be limited to 12.5 kc.

In inverter circuits, if the margin angle is small, the frequency limit becomes much lower. As the margin angle is reduced, the initial inverse voltage also becomes less which has the effect of increasing turn-off time. If the margin angle of an inverter were 10 electrical degrees and the turn-off time was 20 μsec, maximum frequency would be 1.39 kc.

Forward switching power loss contributes to average heating and the average current must be reduced as frequency is increased in order to maintain a constant power loss. If the L/R (inductance-reactance) time constant of the circuit is appreciably longer than the turn-on time of the rectifier, the forward switching power loss will be negligible. However, if the L/R time constant is short so that the build-up of current is determined by the collapse of voltage across the rectifier, considerable energy can be dissipated in the rectifier. This energy can be predicted by the following formula:

$$\text{Energy} = 0.65 \text{ by } 10^{-6}\, V_m I_m \text{ watt seconds} \tag{4}$$

where

V_m = anode voltage immediately prior to switching
I_m = anode current immediately after switching

The following example illustrates a calculation of turn-on power:

Circuit	3-phase bridge inductive load
Frequency	400 cycles
Load current	20 amperes
V_m	200 volts
I_m	20 amperes
I_{avg}/cell	6.7 amperes

The average power due to turn-on power would be:

$$P = 400(200)(20)(0.65)(10^{-6}) = 1.04 \text{ watts}$$

This means that for a given fin size as shown in Fig. 11, the average current would have to be reduced by the amount necessary to reduce the average power loss by 1 watt. This can be determined from Fig. 9.

In a similar manner, switching power loss at the end of the conduction interval also requires derating of forward current. At the present time, not enough information is available to predict the energy dissipated during the turn-off interval but it should not exceed turn-on energy because tests indicate that the time required for the rectifier to regain its high impedance state in the reverse direction is less than the turn-on time.

SERIES AND PARALLEL OPERATION

Since the controlled rectifier will turn on without a gate signal if the forward blocking voltage rating is exceeded, series operation requires a means of forcing voltage sharing. Matching is not practical unless the voltage is derated substantially. A resistor can be used in parallel with each series cell. The following formula can be used in order to determine the value of resistance required.

$$r = \frac{30(nV_R - V_{pk})}{n-1} \tag{5}$$

where

V_R = rated cell forward blocking voltage
V_{pk} = maximum forward circuit voltage
n = number of series rectifiers
r = maximum shunting resistance in ohms

The shunting resistances should be within 2% tolerance of each other. For satisfactory sharing of high-frequency transient voltages, it is recommended that 0.01-microfarad capacitors be also connected in shunt with each cell.

Controlled rectifiers may be operated in parallel provided that some means of current sharing is provided. This can be accomplished by external circuit means or by using factory-matched cells. Matched cells are also selected for firing at low anode voltage. When operating in parallel, the width of the firing pulse must be sufficient to allow the current through each cell to reach the minimum sustaining value of approximately 50 milliamperes.

Conclusions

The ratings of the silicon-controlled rectifier, extending up to 16 amperes at 300 volts, give rise to many new fields of application for semiconductor devices. The replacement of thyratrons, magnetic amplifiers, and relays in such applications as static switching, motor speed control, inverters, and voltage surge suppression are a few of the many possible applications.

While far from being complete, the characteristics and ratings have been presented to assist the circuit designer in this work and as a guide for the correct and successful application of this new device.

CCITT Recommendations for Multichannel Radio Relays and White Noise

CHARLES A. PARRY
MEMBER AIEE

Synopsis: The recommendations of the International Telegraph Consultative Committee (CCIT) and International Radio Consultative Committee (CCIR) now extend into virtually every phase of communications, and are becoming of increasing significance to the radio-relay engineer. Of particular interest is the hypothetical reference circuit proposed as a guide for system design. It is pointed out that recommendations with respect to this reference are intended primarily for international circuits, and do not necessarily apply to all operational conditions. Optimum design would suggest that limits be established on the basis of actual performance requirement.

Because of its significance in radio-relay design, the channel signal-to-noise ratio is considered in some detail, and both nonlinear and thermal components of the noise are discussed. The nonlinear noise is shown to be dependent on both the number of channels and the multichannel signal power (associated with traffic). Distributions for this are given. The effect of relative periods of maximum fading and traffic, and the proportions and periods of maximum international traffic are also taken into account. It is noted that nonlinear noise can also be produced by selective fading, but at present this does not appear to be calculable with any reliability.

The thermal noise component in the channel output is influenced by the amplitude of the received radio-frequency (r-f) signal. During periods of worst fading, on which the design must be predicated, Rayleigh noise distributions may be expected over several links simultaneously, and there is considerable advantage to be gained from diversity operation. It will be shown that the over-all distribution of the multilink system appears to be substantially independent over a fairly wide range, both of the number of fading links and the proportion of these to the nonfading links. This suggests a general design limit for basic system planning.

On this basis it is recommended that the (channel) signal-to-weighted thermal or nonlinear noise ratio should exceed 40 db (decibels) for 99% of the busiest hour for the principal circuits, considering only contributions from the radio equipment. When pre-emphasis and de-emphasis are also taken into account, the basic design requirements for the top channel of an S section system are then: 64.5 db for the signal-to-unweighted thermal noise in an unfaded link; and $(30.5+10 \log S)$ db for signal-to-unweighted nonlinear noise in each section. These figures apply closely for systems from 10 to 40 links in which second-order distortion is predominant.

The use of white-noise testing and its particular relation to these various factors is discussed. It is suggested that the rms power of this signal for an N channel system should be $(-5.0+6.6 \log N)$ dbm0 (db referred to one milliwatt). The signal-to-noise ratio expected in the operational system is readily related to results obtained by this process. The white-noise test is a useful tool under controlled conditions, but measurements in the field may prove unsatisfactory due to the difficulty in separating thermal and nonlinear noise components.

THE INCREASING participation of radio-relay engineers in the planning of national and international telecommunication networks in many parts of the world has emphasized the importance of the work undertaken by the International Telegraph and Telephone Consultative Committee (CCITT).

The recommendations of this group are of special interest, particularly those with respect to the hypothetical reference circuit, while those considerations which relate to per-channel signal-to-noise ratio are of prime concern in system planning.

In order to derive this ratio it is necessary to consider such factors as the distribution of traffic volume, distribution of carrier signal due to propagation, periods of maximum traffic and fading, the proportion of international traffic, and the effects of base-band noise equalization. In addition it is necessary to establish the absolute value for this ratio. One method of determining this is to consider loss of intelligibility and consequent operating time.

It is the purpose of this paper to examine these factors, with a view to establishing a guide in basic system planning. In addition, the use of white-noise testing and the relation of this to required performance parameters is considered.

The discussions are intended to apply to frequency-modulated (FM) systems using frequency division (FD) multiplex.

The CCITT and Recommendations

The International Telephone Consultative Committee (CCIF) and the CCIT were formed officially in 1925 for the purpose of co-ordinating studies being conducted by the various European telephone administrations, and for proposing solutions to the difficulties arising from differences in language and equipment. Since that time they have met regularly, and today all the large administrations in Europe and the Americas and many other parts of the world are members. Although the primary functions remain unchanged, the scope has been broadened to keep pace with the complexity and progress of modern communications.

The CCIR was established in 1927 to study technical and operative radio problems of international interest. At the Atlantic City, N. J., conferences of 1947 this body was reconstituted under the framework of the International Telecommunication Union, and thereby came under the same administrative structure as the CCIF and the CCIT. Recently, the latter two groups were brought together as the CCITT. Some of the responsibilities and functions of these bodies have already been described in the literature.[1,2]

It is the function of the CCITT to think in terms of international operation and to disregard purely national matters, although national aims naturally influence many decisions. National procedures are left to the discretion of the administrations concerned, but many of the studies and recommendations of the CCITT can be applied usefully to purely local networks.

In order to resolve communications problems, it has been the practice to set up groups charged with the responsibility of making specific studies. The reports of these study groups are then brought out as specific recommendations by the parent body concerned, that is the CCIF, CCIT, or CCIR. These recommendations have been improperly referred to on many occasions as "standards." This is not the case. The recommendations reflect the best compromise based on composite and sometimes conflicting views, as well as on the best known state of the art. They also suggest the techniques and operative limits which will permit international circuits to be compatible with each other.

Today, with the rapid expansion of international circuits and American participation in communications planning in many parts of the world, there has come the need for a wider knowledge and under-

standing of these recommendations. They have always been available in printed form and today all volumes may be obtained in the three principal languages, English, French, and Spanish.[3,4] Containing, as they do, the questions, the reports covering the state of the art, and the recommendations arising from a study of these matters, they are not only a working guide for the engineer, but also an invaluable library of up-to-date condensed information, covering virtually every phase of communications.

In order to evaluate both systems and equipment, the CCIF orginally proposed a hypothetical fictitious reference circuit. Orginally suggested for wire and cable circuits, the concept automatically was accepted for radio-relay planning. The reference circuit is about 1,500 miles long, is divided into a specific number of homogeneous sections, and has a specific number of base-band (audio) patches and frequency translations.[5] The proposed form of these circuits is shown in Fig. 1. For the purpose of analysis they may be considered to consist of 50-microwave links of equal length. This reference circuit concept has the advantage of providing a design framework for both the equipment designer and the system planner. In addition, it is invaluable to the customer as a guide to establishing performance guarantees. The danger in proposing the reference circuit lies in its indiscriminate application to all systems regardless of their actual operational need. It should be recognized that circuits required for international service will demand the highest performance standards. There seems little doubt, however, that somewhat simpler operational requirements exist on routes which do not carry international traffic. Further, the relative number of international circuits which a route has to carry is quite small as can be inferred from Table I.[6] Hence, it is unlikely that there should be any need to impose maximum requirements on all circuits of the international route, nor does it seem reasonable to impose "international" limitations on the "worst" channel in the system. It would seem more in keeping with good engineering principles to apply such limits to the best 5% of channels. It should be evident that different sections and circuits of the national network should have different performance limits in keeping with operational needs. Many private industrial systems are included as part of the national network, e.g., those used by utility companies. Performance standards for these should be based on their own need, not on those applicable to the national network. This has been discussed previously by the author[7] and some suggestions along these lines have been made.

The reference circuit itself is of course only a guide toward detailed specifications for radio-relay systems and for international operation. Reference

Table II. Some Basic Requirements for the International Circuit

Item	Limit
Reference equivalent	≤7 db
Variation of equivalent	±1.7 db
Band of frequencies effectively transmitted*	300–3,400 cycles
Group delay (t)	<150 milliseconds
Phase distortion (from the group delay t)	$t_m - t$ min <10 milliseconds† $tM - t$ min <5 milliseconds
Stability of transmission	±1.7 db
Maximum allowance power at a point of zero relative level	
1. Telephony	not specified
2. Telegraphy	5 milliwatts
3. Photo telegraphy	amplitude modulation 1 milliwatt frequency modulation 0.1 milliwatt
4. Voice-frequency signalling	−26 dbm 0 for continuous tone
Duration of interruption in change-over in stand-by power supply	<150 milliseconds

* The CCIF defines the limiting frequencies as those for which the loss is 8.6 db greater than that at 800 cycles. In the United States, limiting frequencies which are 10 db down with respect to 1,000 cycles.

† m = nominal minimum frequency effectively transmitted. M = nominal maximum frequency effectively transmitted. min = minimum frequency corresponding to minimum group delay time.

should be made to the appropriate volumes of the CCIR and CCIF for this purpose.[5, 8] However, some of the factors which are of prime interest to the radio-relay engineer have been included here. Table II, for instance, lists some of the more important circuit requirements; Fig. 2 shows the over-all frequency response of a channel; Fig. 3 shows the frequency arrangements for the channels of frequency-division multiplex (FDM) systems intended for use over coaxial cables or radio relays; and Table III lists the recommended deviations for FM systems as well as suggested intermediate frequencies.

The Total Noise and Its Proportions

Because the signal-to-noise ratio (as measured at the output of each channel) determines so many basic system-design parameters, it has remained of fundamental importance to the radio-relay engineer. However, the most suitable ratio has never been adequately defined and still remains subject to study and investigation. On the other hand, this should not be taken to imply that satisfactory values for signal-to-noise ratio are not used by the various administrations when designing communication systems. The principal sources of noise which must be taken into account are shown in Fig. 4. The CCIF initially recommended that the noise power in a channel for circuits on coaxial cable should not exceed 10,000 picowatts (micromicrowatts, $\mu\mu$w) at a point −7 db0 (db with respect to a point at zero relative level) under conditions that were somewhat obscure. For open-wire circuits much higher noise levels were permitted. At the Geneva Conference of 1954,[9] a big step forward was made by recommending that the reference signal-to-noise ratio should be based on the long-term mean value. This provides a working point which can be used irrespective of the distributions (in time) with which the noise is usually associated. However, while this is a convenience when adding the noise from various sources, it does not appear to be entirely adequate when it comes to specifying satisfactory performance. At this time also it was considered that noise should be measured during the "busy" hour, and a proposed distribution was given; see Fig. 5. It was also intended as a guide for radio-relay systems. The CCIR[5] in 1956 indicated a general distribution which it considered gave satisfactory telephone service. This is also shown in Fig. 5. Neither of these

B—Distribution of total noise suggested for busiest hour. Noise includes contributions from multiplex

distributions is entirely suitable for the design of radio-relay systems, and at present the only real solution is to aim for a performance agreeable to administrations and consistent with good engineering practice. It is the present intention to examine further this question of the signal-to-noise ratio.

The suggested proportions of mean noise power in the channel of the hypothetical circuit at a point of zero relative level have been given by the CCIR[5] as follows: 1. 2,500 $\mu\mu$w due to the multiplex equipment; 2. 5,000 $\mu\mu$w in the busy hours in the absence of fading; and 3. 7,500 $\mu\mu$w in any hour.

These proportions recognize that periods of maximum traffic and worst fading rarely coincide. This effect is indicated in Fig. 6 and is also discussed later.

Traffic and Nonlinear Noise

The distribution of nonlinear noise (also referred to as intermodulation and distortion noise) among the channels of the multichannel system, due to the transmission of the complex signal through nonlinear elements has now been treated by a number of authors.[10-12] It can be shown that the noise power p_n which falls in a particular channel is given by:

$$p_n = KyP^{\beta} \tag{1}$$

where K is a constant, y a factor depending upon the relative position of the channel, P the mean power of the complex signal, and β the order of distortion producing the noise. When the distribution of P is known, that of p_n readily follows.

The distribution of mean power of the multichannel signal during the busy hour was probably first worked out by Holbrook and Dixon[13] and later by Jacobsen.[14] A recent examination of these data[7] has shown that for a fixed probability of occurrence, the mean power closely bears an exponential relation to the number of channels. Representative curves drawn up on this basis are indicated in Fig. 7. The absolute value of power is related to average talker volume and this has been the subject of investigation by several administrations.[9] In particular, Subrizi[15] has demonstrated that there has been an apparent increase in talker volume since Holbrook and Dixon's original work, probably associated with changes in user habits and improvements in equipments. Subrizi arrives at a figure of −15 dbm0 for toll circuits, a value which has been used in the derivation of the mean power curves of Fig. 7. The distribution of the mean power (with time) for a fixed number of channels is approximately Gaussian, so that the long-term average is given by $Vm+0.115\sigma^2$, where Vm is the median and σ^2 the variance. This is also shown in Fig. 7. In addition, curves of the rms test-tone load capacity have been included. Curve f is that obtained from reference 13, using an overload expectancy (as defined by Holbrook and Dixon) of about 10^{-5}. The effects of limiting on all channels is included. Curve e is that derived by the author[7] using an overload expectancy of 10^{-3} and based on Subrizi's figure for the average talker. An allowance is also made for limiting. However, curves a, c, and d, for the mean power, do not include the effects of limiting and as such, therefore, provide a small design margin. It should also be pointed out that the figure used for average talker volume is still probably 4 to 5 db too great for short-haul circuits[15] so that the mean power curves of Fig. 7 are probably much too conservative when applied to short links.

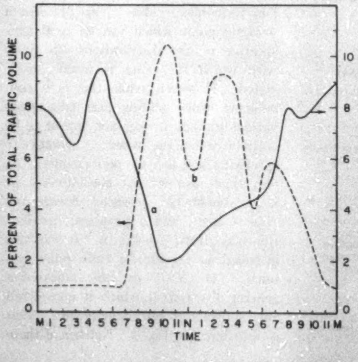

Fig. 6. Curves prove that, under typical conditions, periods of maximum traffic and worst fading do not coincide

Curve a = typical diurnal fading on a microwave link; smoothed data[22]

Curve b = total traffic volume based on averaged data for 25 principal American cities taken from information supplied by the American Telephone and Telegraph Company

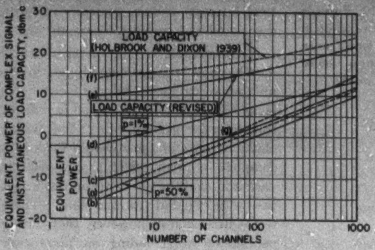

Fig. 7. Distribution of equivalent power of multichannel signal during the busy hour. Curves are based on an activity factor $\tau=0.25$. p is the probability that ordinate will be exceeded

Curve a = median value of the distribution
Curve b = power assumed for signaling, carrier leaks, and pilot tones
Curve c = long-term mean power of distribution
Curve d = power in the signal due to traffic alone, exceeded 1% of the time

Curve f = load capacity recommended by Holbrook and Dixon,[13] and based on peak-to-rms ratio with probability 10^{-5}. Includes limiting
Curve g = rms level of white-noise test signal suggested by CCIR
Curves a through d apply for uncontrolled volumes with effects of limiting not included. Long-term mean power of single talker −15 dbm0

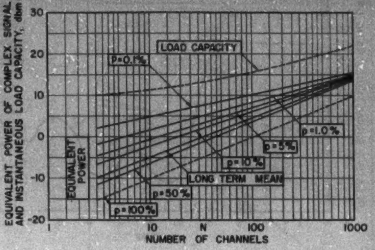

Fig. 8 (right). Curves similar to those of Fig. 7 but recalculated to include effects of the tones of curve b. Suggested for practical long-haul toll circuits

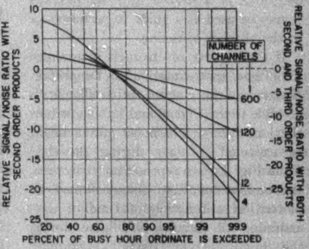

Fig. 9 (right). Distribution of nonlinear noise during busy hour shown as function of the number of channels (based on Fig. 7)

The signal transmitted to line includes carrier leaks and signaling tones, which have not been taken into account in deriving the data for Fig. 7. Some allowance must be made for these signals in order to establish practical design curves for the complete multichannel signal. The CCIF has proposed in-band signaling for international circuits, so that the net effect of signaling tones during the busy hour will be negligible. However, there are systems using out-of-band signaling with "tone on" during speech. The maximum power for a continuous signaling tone as proposed by the CCIF[16] is −26 dbm0, the value which will be assumed for an out-of-band tone. The CCIF also gives −14.5 dbm0 as the limit for the combined effect of carrier leaks in a 12-channel system which, on a power additive basis, averages −24 dbm per channel. The combined effect of leaks and tones is then −22 dbm0 per channel. If some margin is allowed for various discrepancies, a figure of −20 dbm0 per channel would seem reasonable. It is therefore suggested that, in a system with all channels busy, the net effect of all these additional tones may be taken as −20 dbm0 per channel, also shown in Fig. 7. The mean power due to these tones may now be combined with the distribution curves established for speech alone (see Fig. 7) in order to obtain the net distribution for the signal transmitted to line. This has been performed and the result is given in Fig. 8. The data have been smoothed and the nearest straight-line approximations used. The result is a rather too rapid convergence for very large numbers of channels, but it is considered that the error involved is sufficiently small to be neglected in favor of the exponential convenience.

Most designs are based on the $p=1\%$ curve, so that the effect of the additional tones is virtually negligible when the number of channels is small. For large numbers of channels, however, the effect of the tones is more significant, and a substantial part of the power is associated with the spurious signals.

The curves of Fig. 8 give the distribution of P in equation 1. The noise distribution for various orders of distortion is now readily obtained since the noise is proportional to $P\beta$. It is immediately apparent that the noise distribution due to traffic is dependent both on the order of distortion and the number of channels. This is shown in Fig. 9. Since the CCIF has suggested that the reference signal-to-noise ratio should be based on the long-term mean value, the curves of Fig. 9 have been prepared on this basis. In a practical system, it may be expected that $3>\beta>2$, so the ordinate scales of Fig. 9 have been provided for the two conditions: 1. the more usual case when second-order distortion predominates and $\beta=2$; and 2. the general case when both second- and third-order distortion are present, and the net distribution lies about half way between those which are obtained for $\beta=2$ and $\beta=3$. The curves neglect the effects of overload distortion. Noise from this source would tend to increase the slope of the curves, but in practical systems no noticeable effects would be expected for abscissas less than 99%. The influence of bandwidth restriction[17,18] is also disregarded here since the system design usually permits this to be made negligible. It should be recognized that the distributions of Fig. 9 apply to any part or parts of the over-all circuit, only the absolute value being affected by the number of circuits in tandem. There will, however, be a slight change in distribution as the circuit length is extended, since usually third-order effects become more noticeable. However, Fig.

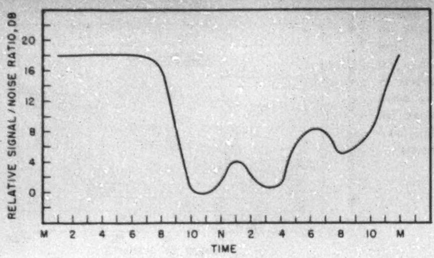

Fig. 10. Possible daily variation in long-term mean nonlinear noise power

9 may be used as a guide to performance in the absence of fading.

If the number of channels is assumed to a first approximation to be proportionate to the volume of traffic, it is possible to use Figs. 6 and 7 to show how the long-term mean noise power might be expected to vary during the day. From Fig. 6, for a representative system, the number of busy channels may be plotted as a function of time of day, assuming all channels are busy during the "busiest" hour. Using this number, the variation in the long-term mean signal power may be obtained with the aid of Fig. 7. The variation of mean noise power is then obtained by applying equation 1. In order to take a representative case, this process was carried out for a 60-channel system, with second-order distortion predominant. The results are in Fig. 10. The residual noise during quiet hours is due to the presence of carrier leak. In deriving the curve of Fig. 10, the carrier leak is taken as −24 dbm0 per channel, and signaling tones as −26 dbm0 per busy channel. This curve probably gives no more than a general picture of the probable diurnal variation, and many departures could be expected in practice. So far, very little information is available on these statistics.[19]

A further factor, the hours of usage, cannot be disregarded. It is extremely unlikely that international traffic would be carried during the periods of maximum local traffic. In the absence of a specified correction factor for this, it is suggested that the loading be based on the number of channels, excluding international circuits. It can be expected in practice that the number of busy channels will never exceed this, since operation of the international circuits will occur at a time when there has been at least a commensurate decrease in the number of local channels in use. This correction is suggested in order to lead to optimal design of radio-relay systems.

Nonlinear Noise Due to Propagation

Periods of deep fading are frequently attributable to multipath effects with consequent distortion and nonlinear noise. Means for calculating this when the specific conditions of fading are known have been derived.[20, 21] However, a detailed study of the phenomenon leads to the conclusion that at the present time it is not possible to derive an expression for this noise from the depth and rate of fading alone.[21] It is quite likely that under certain conditions, noise from this source may be much greater than that associated with either the input thermal noise or with nonlinear noise arising from distortion in the equipment itself. Unfortunately, apart from narrow beams and obstruction-free paths, there seems little which can be done either to predict or protect in this situation. Medhurst gives a simple expression for the maximum distortion due to a deep fade associated with a single echo, assuming a white noise signal. His expression for the noise-to-signal ratio N/S in the top channel of the FM system is

$$N/S = t^2 \times d^2 \times f_d f_m \times 0.14(2\pi)^2 \qquad (2)$$

(voltage ratio)

where f_d is the frequency deviation in cycles, f_m the highest base-band frequency in cycles, t the delay in seconds, and f_d the depth of fade, defined as the ratio of unfaded to faded signal amplitudes. A quick calculation will show that even for an echo of only 1 millimicrosecond and a fade of 30 db, wide-band systems will suffer severely from this cause.

Thermal Noise at Receiver Input

The principal source of thermal noise is that associated with the input to the radio receivers. This means that the per-channel signal-to-thermal noise ratio is directly proportional to the carrier power (at least over the ranges of practical interest) and is, therefore, directly associated with propagation conditions.

A considerable amount of experimental data has now been presented in relation to microwave circuits[22−28] but much of this lacks definition and detail and is difficult to relate the general case. The fading characteristics of the separate links in a complete system exhibit considerable variation, and the net distribution cannot easily be related to one link. There seems little doubt, however, that during periods of worst fading on microwave circuits, a Rayleigh distribution is approximated, and this permits an approach for the worst case. Gudmandsen and Larsen[24] indicate that the distribution on specific circuits was more severe than the Rayleigh for only 7% of the observed days and 25% of the observed hours (maximum figures). Cabessa, Byam and Millar, Halena, and Kaylor, to mention a few, also indicate this tendency toward Rayleigh distribution. Gough, on the other hand, observing the band from about 80–200 megacycles, suggests a Gaussian distribution as suitable for diurnal variations, but his sampling interval (from 1 to 2 minutes) is perhaps too long compared to the sampling period to show the fine grained fading structure.

Fading exhibits both a diurnal characteristic, as shown in Fig. 6, and a seasonal variation. Severe fading usually occurs for only a relatively short period of the year. During less severe fading periods, the distribution tends toward Gaussian, with a standard deviation (diurnal) of less than about 3 db. The nature of the Rayleigh distribution is such that a rather large fading margin must be provided if satisfactory reliability is to be achieved. Consequently, a design based on worst fading periods will be more than adequate for the rest of the time.

The data which are presented relative to Rayleigh fading generally indicate that with this type of fading, the median signal level is depressed several db below the normal unfaded value. Theoretically it can be shown that the long-term mean noise power with Rayleigh fading is approximately 10 db greater than the noise when there is no fading at all,[8] a figure which seems to agree reasonably well with the value indicated in the literature. This leads to the following expression for the relation between the mean noise power N_m at the end of m links in terms of the mean noise power N_o in one link without fading

$$N_m = m N_o \left[10 \frac{n}{m} + 1.44 \frac{m-n}{m} \right] \qquad (3)$$

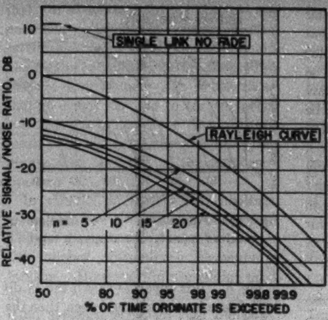

Fig. 11. Distribution of thermal noise in channel due to independent Rayleigh fading on n links and no fading on 50 −n links

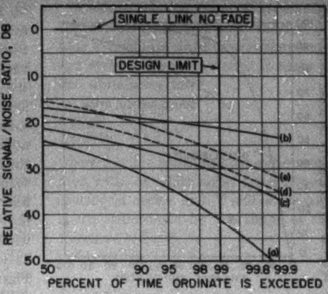
Fig. 12 (right). Distribution of thermal noise in channel due to fading and nonfading links. Selector-type diversity is assumed

Curve a = 15 links with Rayleigh fading and 35 without
Curve b = correlated Gaussian fading on 25 links, 25 without
Curve c = same as curve a but assuming dual diversity on all links
Curve d = independent Rayleigh fading on all links of a 10-link system with diversity
Curve e = same as curve d but with 5-link system



where *n* is the number of links with Rayleigh fading and the factor 1.44 is an experimentally observed correction. Distributions based on this relation are shown in Fig. 11. The necessary allowance has been made for the 1.6-db difference between the mean and the median in the Rayleigh distribution.[28]

Severe fading is usually associated with seasonal characteristics, so that it can be expected that this will occur over a relatively long portion of the route. A study of weather conditions over typical 1,500-mile paths indicates that nearly one third of this might be subject to severe conditions at any one time. Accordingly, the reference for severest fading conditions will be based on 15 fading and 25 nonfading links. The net distribution due to independent Rayleigh fading on such a system is shown in Fig. 12, and can be assumed applicable to any of the worst hours.

When the fading range is small, it is usually associated with changes in refractive index which occur over a considerable area. This implies possible correlation of the fading phenomena, which generally exhibit a Gaussian distribution. Accordingly, it will be assumed that during these periods the distribution will be due to 25 links with Gaussian fading, and 25 links with signal about equal to the median value for one link. In the worst case the fading will be correlated and this is shown in Fig. 13.

During severe fading it has been found that virtually the full effect of uncorrelated diversity action can be achieved.[24,25] The theoretical improvement is readily available from the literature.[21] The effect of dual selector-type diversity is also shown in Fig. 12. It is readily seen that a system designed on this basis will be quite satisfactory when correlated Gaussian fading occurs over most of the route.

The net distribution indicated by curve *c*, Fig. 12, is closely Gaussian over the range of interest. It can be seen also from Figs. 11 and 12 that the net distribution does not appear to be substantially affected even for fairly large changes in the number of links, the proportion of fading links, or, when fading is not severe, by the change in the general form of the distribution. This suggests that a generalized design procedure based on curve *c* of Fig. 11 might be used for system planning. The distribution would be only slightly different when a short section consisting of only a few links, is being considered. Of course, the mean value would also change as indicated by equation 3. Using this and Fig. 11, the design limit for a single unfaded link can be easily established.

The Noise Limit

One of the difficulties which is presented to the system engineer once a noise distribution has been determined, is to establish the absolute value for some degree of reliability. The general figure of 50 db for signal-to-noise ratio has been accepted as suitable but its origin is obscure and just whether it is in excess of real requirements has never been satisfactorily determined.[7] The question then is, just what does a specific signal-to-noise distribution mean as far as the listener is concerned? Burrill[29] has made some useful observations in terms of judged listener quality for program transmissions but these data are not entirely applicable to the telephone channel. A considerable amount of information has been obtained on the effect of various signal-to-noise ratios on articulation.[30−34] After studying this literature, it is apparent that satisfactory and intelligible speech may be conducted with extremely high noise-to signal ratios; much higher than is customarily associated with even poor-quality voice channels. When the noise is interrupted, corresponding for instance to the effect of short (less than 1 second) deep fades, the tolerable level of noise is great enough[33] to preclude any consideration of the effect of these fades on intelligibility in practical systems. What, therefore, should be the judgment criteria? It is known that noise will reduce articulation, and with this there is an increase in the time taken to understand a sentence.[34] This leads to the concept that the system might be designed on the basis that the increase in time during a busy hour from this cause should not exceed, for example, 1%, a figure in keeping with other design parameters related to the busy hour. It is interesting to note that Collard[35] suggested time efficiency as a general criterion of transmission performance, but his paper did not appear to receive much further attention. The increase in time is related directly to the decrease in intelligibility and may be obtained from curves of intelligibility and articulation.[34] Fig. 14 shows intelligibility versus sound and syllable articulation.[9,34] The CCIF

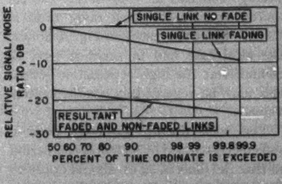


Fig. 13. Distribution of thermal noise in channel due to correlated Gaussian fading. System of 50 links assumed with fading on 25 links simultaneously and no fading on remaining 25 links

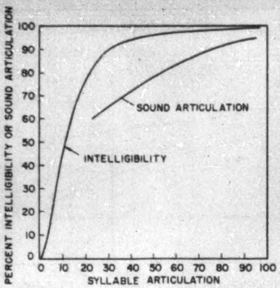

Fig. 14. Sentence intelligibility versus sound and syllable articulation

uses 80% sound articulation as a reference figure which corresponds to about 96% intelligibility on these curves.[1]

Fletcher[31] has determined the articulation for a typical commercial telephone circuit over a 9-db trunk. In addition, he has derived curves showing the effects of white noise received over an ideal circuit and these data may be used for evaluation of noise limits. Fig. 15 is based on this information. The intensity level of received speech when the talker is in the presence of typical room noise will probably be between 70 to 90 db, with maximum articulation above 95%. Fig. 14 shows that this corresponds to almost 100% intelligibility.

It can be seen that the distribution of noise with time will cause a corresponding distribution of intelligibility. If the noise during the busy hour causes a maximum loss of 2% in intelligibility, it can be expected that the average loss would be 1%, corresponding closely to an increase of 1% in operating time. Using Fig. 14, the 2% limit is reached with a syllable articulation of about 68%. Fig. 15 indicates that this is true when the noise is approximately 14 db below speech level. This noise level is sufficiently above room noise[36] for the latter to be negligible. If we assume an average toll call at −15 dbm0, the required signal-to-weighted noise ratio is 32 db. Since the curves of Fig. 15 are for the ideal case and in practice tend to compress at the high articulation levels, this may be regarded as a conservative value.

The noise during the busy hour is sufficiently defined by 99.9% of this period so that the limit of 32 db should apply to the 99.9% abscissas on the distribution curves. It is more convenient, however, to speak in terms of the ratio which is exceeded for 99% of the time. Using Figs. 9 and 12 as a guide, a value of 38 db is suggested. It would also appear from examination of Figs. 14 and 15 that there would be little practical effect for variations in this value of as much as ±5 db. On a similar basis, for private industrial systems where limits might be somewhat relaxed, a signal-to-weighted noise ratio of 33 db exceeded for 95% of the hour should be adequate. A limiting value for any design (30 db for 95% of any hour) seems reasonable. These figures do not consider military applications for which a signal-to-weighted noise ratio of as low as 13 db may be acceptable.[37] Figs. 14 and 15 substantiate the fact that short periods with extremely high noise levels are not likely to affect intelligibility appreciably. It is also apparent that different noise distributions with the same mean value may produce different articulation loss. Thus, on the basis of present reasoning it would appear undesirable to try to specify performance in terms of the long-term mean value alone.

Base-Band Noise Equalization

The practice of using pre-emphasis and de-emphasis networks in FM systems has come about in order to redistribute the noise more evenly over the base band. Reference has been made elsewhere to base-band noise equalization, and a method for the calculation of improvement in top channel noise has been outlined.[38] The CCIR[5] has suggested tentatively that the maximum equalization between the top and bottom ends of the band should be 10 db. This corresponds closely to the suggestion that the maximum insertion loss of the network should be about 16 db.[38] This network will also produce a virtually flat noise spectrum over the base band. The following improvement in the top channel signal-to-noise ratio is obtained: 1. Thermal noise only, 3 to 5 db; 2. Second-order nonlinear noise only, 6 to 5 db; and 3. Equal thermal and nonlinear (second-order) noise, 4 to 5 db.

These figures are for the noise due to the radio equipment alone, and are used in the following paragraphs.

Total Noise Distribution

With an absolute value for the noise determined and with knowledge of the distributions, it is a relatively simple matter to establish fundamental design parameters. In the first place, it may be assumed that the multiplex equipment produces a mean noise power of −56 dbm0, with a distribution probably similar to that laid down by the CCIF and shown in Fig. 5. It is apparent that if the 38 db 99% figure is used as a reference, then the influence of the multiplex is virtually negligible. An increase of 1 db in the ratio for radio equipment alone is adequate to take this latter into account. An additional 1 db is suggested as a margin, resulting in a figure of 40 db for radio equipment alone.

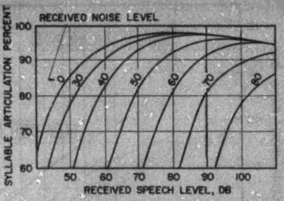

Fig. 15. Articulation as a function of received noise level and speech level

It is difficult to ascertain whether the nonlinear noise distribution of Fig. 9 and the thermal distribution of Fig. 12 should be considered as acting together or separately. The evidence indicates that maximum fading during periods of maximum traffic occurs as an exception, and it is doubtful if a general design recommendation should be established on this basis. Nevertheless there is always some traffic during fading, just as there is always some fading during the busiest hour. Furthermore, it is apparent that the distribution which may apply to the over-all reference circuit will not apply precisely to a small section. During periods of worst fading this again will surely coincide with hours of maximum traffic. However, if the two distributions do occur and the noise powers corresponding to the 1%-of-time points are made equal, there is no appreciable degradation of the system performance and the matter would seem to be largely academic. Indication is shown by the combined distribution in Fig. 16. Thus, it is sufficient

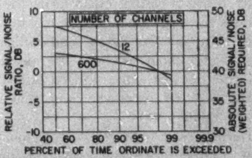

Fig. 16. Combined distribution of thermal and nonlinear noise assuming the separate distributions of Fig. 12, curve (c), and Fig. 9 occur simultaneously. Noise due to each separately, is adjusted to give 40-db signal-to-noise ratio for 99% of the time

that the signal-to-weighted thermal and nonlinear noise ratios considered separately, associated with the radio equipment alone, should be better than 40 db for 99% of any hour. Fig. 16 also shows that it is not suitable to try to specify performance in terms of the long-term mean value alone, because this must then be specified in terms of the number of channels.

In general, it appears that nonlinear noise adds power-wise along the system. That is, the noise power is proportional to the number of nonlinear elements on tandem. However, voltage-adding products may become significant on long wide-band systems, in which case the power is proportional to the square of the number of contributing elements. On the basis of power addition, the signal-to-weighted noise ratio required in the top channel of each link or section of the systems will be $(40+10 \log S)$ db where S is the number of homogeneous sections. The general design requirement, assuming second-order distortion, is then $(30.5+10 \log S)$ db for the signal-to-unweighted nonlinear noise ratio prior to the application of base-band noise equalization. This reference ratio should be established for the multichannel signal given by the 1% curve of Fig. 8.

In the case of thermal noise, it is seen from Fig. 12 that the fading margin per link should be 41 db for a nondiversified system and 31 db with dual diversity, to cater to the worst hours during the year. The latter figure corresponds to a design value in the top channel for signal-to-thermal noise (unweighted) prior to the use of pre-emphasis and de-emphasis of 64.5 db per unfaded link when base-band noise equalization and weighting are taken into account. This requirement holds closely for a wide variation in the number of links and the proportion of fading to nonfading links, but for fewer than ten links new curves should be drawn up in a manner similar to those of Fig. 12. When the operating frequencies are sufficiently low and the path conditions will not produce severe fading, representative curves similar to those of Fig. 13 can be drawn up, e.g., Gough's data.[36] If uncorrelated Gaussian fading is expected new distribution curves may be drawn.[37]

Propagation Outage Time

Thus far no mention has been made of outage time due to deep fades. This has not yet been defined by the CCIR, nor has the matter been covered in the literature. With the FM system, deep fades below the threshold will cause the noise to rise to a very high value. As already mentioned, with the rather high signal-to-noise ratio pertaining during the worst hours, it is extremely unlikely that this noise increase will cause appreciable interference with speech. The sudden loss of signal tends to clip an element of time from the speech sounds. The effect is likely to be more significant in any loss of articulation. In addition, it is customary for the multichannel system to carry telegraph signals and these may be disrupted for the outage period. The acceptable percentages of time for these phenomena have not yet been determined. However, if the frequency and average duration of fades[38] are considered in conjunction with the r-f signal distribution which dictates Figs. 11 and 12, it would seem reasonable to believe that if this period does not exceed 1% of any hour (during conditions of worst fading), the performance would be acceptable. The implication is that the threshold r-f signal should be not less than that corresponding to the 99% abscissas of Fig. 12. It should be mentioned, perhaps, that this criterion probably would apply irrespective of the absolute signal-to-noise ratio pertaining to the threshold carrier.

White-Noise Testing

The principle of white-noise testing has now been well established in the art.[7,39] The CCIR[5] tentatively has suggested that the rms value of the test signal for systems of more than 240 channels should be given by $(-15+10 \log N)$ dbm0, where N is the number of channels (curve g of Fig. 7). It would be more appropriate however, to choose a relation which would fit the 1% curve shown in this figure. The rms signal would be $(-5.0+6.6 \log N)$ dbm0 and is suggested because, as already indicated, it seems preferable to predicate the design on the noise limits to be reached during 99% of the busy hour. Furthermore, since the behavior beyond this percentage is not so important, it is implied that the test signal would also be the maximum likely to be transmitted, and as such, would include effects due to overload distortion. The per-channel transmission level in the operative system also readily follows from the 1% curve of Fig. 8. A test signal corresponding to the long-term mean power of the distribution shown in Fig. 8, could give quite suitable information concerning nonlinear distortion, but the amplitude would be too small to produce overload effects, and, therefore, it would be of less value in a test procedure.

A simple relation exists which enables the expected signal-to-noise ratio S/N' (due to nonlinear distortion) in the operative system to be determined in terms of the white-noise test:[7]

$$\underset{\text{(weighted)}}{S/N'} = \frac{\gamma b}{X 1.5\ 10^3} N^{(1-\alpha)}$$

where γ is the signal-to-noise ratio measured with the white noise, b the channel spacing in cycles, and X and α are constants determined by the shape of the 1% curve of Fig. 8.

In this case

$X=0.32$
$\alpha=0.66$
$b=4{,}000$

Consequently,

$$S/N' = \gamma N^{0.34}\, 8.4 \tag{4}$$

Since the requirement prior to the application of pre-emphasis and de-emphasis networks is for a signal-to-unweighted noise ratio of 30.5 db, $S/N'=33.5$ db, and the result is

$$3.4 \log N = 24.2 - 10 \log \gamma \tag{5}$$

(second-order distortion predominant)

Equation 5 is, of course, a requirement related to the over-all fictitious circuit of reference. On the basis that the separate noise powers are additive, it is a straightforward matter to determine the requirement for any section or link. The expected long-term mean may be obtained for any specified number of channels (Fig. 9).

The white-noise test presents no special difficulty for equipments connected back-to-back, but there is great difficulty in interpreting results with the equipment on location. If a particularly long section is being tested, it is difficult to avoid the effects of fading, unless particularly favorable conditions are in effect, and there is no satisfactory way of isolating the nonlinear and thermal noise components. The only suitable technique is to test the shortest sections of the circuit during periods of the day when the signal strength is maximum so that the effects of thermal noise can be negligible. The noise powers of the separate links may then be added to estimate the total noise. This technique must also be treated with caution since it is possible that when sections are interconnected, voltage-adding products may become significant. Such a possibility may be determined by careful laboratory testing on the back-to-back equipment. By so doing, the law of addition can be obtained prior to installation and the over-all nonlinear noise for the operative system may be estimated.

Conclusions

The recommendations of the CCITT apply to virtually every phase of modern communications. Of particular interest to radio-relay engineering is the hypothetical reference circuit and the over-all signal-to-noise ratio. It is pointed out that the CCITT recommendations are primarily intended for international circuits and do not necessarily apply to all operational requirements. Distributions of multichannel signal power (associated with traffic) are given and it is shown that the nonlinear noise associated therewith, is dependent on the number of channels. The effect of the relative periods of maximum fading and maximum traffic and the proportion and periods of maximum international traffic, are also considered.

It is suggested that for the optional design of radio relays, the performance limits for international circuits might well be limited to the best 5% rather than the worst channels and that the number of channels on which the traffic volumes are based should exclude those intended for international circuits.

Thermal noise is determined principally by propagation conditions. During periods of worst fading, signal strength exhibits a Rayleigh distribution and there may be uncorrelated fading over a large part of the route. However, during this period, a significant improvement due to diversity operation can be achieved. Severe fading usually produces nonlinear noise due to multipath but at present this effect is not capable of simple prediction. The effects of the numbers of fading links and resultant thermal noise distributions are presented.

The absolute value of signal-to-noise ratio is examined on the basis of the increased operating time due to the loss of articulation in the presence of noise. Thus it is recommended that signal-to-weighted thermal or nonlinear noise should be greater than 40 db for 99% of any hour, excluding the contribution of multiplex equipment. From this and the noise distributions the requirements for a single link may be determined. The improvement due to the use of pre-emphasis and de-emphasis networks is also taken into account. These data lead to the generalized design requirement: the signal-to-thermal noise figure for a single unfaded link should be 64.5 db and the signal-to-nonlinear noise should be $[30.5+10 \log S]$ db where S is the number of homogeneous sections. These figures apply to the unweighted noise in the top channel prior to the use of base-band noise equalization and, within small limits, for systems of 10 to 50 links with second-order distortion predominant.

White-noise testing to determine nonlinear noise is a useful technique under controlled conditions. In the field, however, there may be much difficulty in separating thermal and nonlinear noise components. The preferable rms test-transmission level for an N channel system is $(-5.0+6.6 \log N)$ dbm0. The results obtained may be related easily to the operational system.

Appendix

The following notes are taken from the report of the U. S. Delegation to the Interim Meeting of the CCIR Study Group IX, Geneva, Switzerland, August 18–29, 1958. In particular, they refer to reference 43. They are included here because of their particular significance with respect to the contents of this paper and specifically wide-band radio-relay systems.

Noise aspects of radio-relay systems as related both to hypothetical reference circuits and to real circuits were considered by Subgroup IX-C.

A draft recommendation was prepared to replace Warsaw Recommendation 200. It specifies that the psophometrically weighted[*] noise power at a zero level point in any telephone channel on a 2,500-km (kilometer) hypothetical reference circuit for FDM systems should not exceed the following values (the assumption is made that the hypothetical reference circuits are loaded with uniform white noise at zero transmission level of $-15+10 \log_{10} N$ dbm for 240 channels or more, and $-1+4 \log_{10} N$ dbm for numbers of channels between 12 and 240, N being the total number of channels for which the radio relay system is to be designed):

1. 7,500 μμw mean value in any hour.
2. 7,500 μμw 1-minute-mean power for more than 20% of a month when the fading is severe.
3. 47,500 μμw 1-minute-mean power for more than 0.1% of a month when the fading is severe.

It was also decided that an additional item should be suggested to the Joint CCITT–CCIR Working Party on Circuit Noise for its guidance:

4. 1,000,000 μμw unweighted 5-millisecond-mean power for more than 0.01% of a month when the fading is severe.

It was recommended concerning noise in real circuits, that the psophometrically weighted noise power at a zero transmission level point in the telephone channels of a real FDM line-of-sight radio-relay system of length L km, where L is between 250 and 2,500 km, and for which composition does not differ appreciably from the hypothetical reference circuit, should not exceed $3L$ μμw mean value in any hour, or $3L$ μμw 1-minute-mean power for more than 20% of any month. Also as a planning objective (recognizing that the performance of real circuits may differ from the planning objective and is difficult to measure precisely), the afore-mentioned noise power should not exceed 47,500 μμw 1-minute-mean power for more than $(L/2{,}500)\times 0.1\%$ of any month.

Further study of permissible noise powers for systems of composition differing considerably from that of the hypothetical reference circuit is suggested.

A draft report was formulated on the noise tolerable during very short periods of time in radio-relay systems. Its annex is taken almost exactly from one of the documents submitted by the United States.

A statement was prepared giving the opinion of CCIR Study Group IX concerning noise objectives for radio-relay circuits carrying telegraph signals which was proposed by the Joint CCITT–CCIR Working Party on Circuit Noise. Specifically, it does not accept as an objective that 1,000,000 μμw unweighted-noise power at a zero transmission-level point with an integrating time of 5 millisecond must not be exceeded more than 0.001% of the time per month. It proposes instead, provisionally (as a noise objective for telegraphy), the limit mentioned previously of 1,000,000 μμw unweighted 5-millisecond-mean power for 0.1% of a month when the fading is severe.

---

[*] The level of uniform-spectrum noise power in a 3.1-kc band must be reduced by 2.5 db to obtain the psophometrically-weighted noise power.

Marginal Utility and a Criterion of Performance for Communication and Radar Systems

L. S. SCHWARTZ
MEMBER AIEE

SINCE communication or radar systems, like all systems involving human activity, are subject to the laws of profit and loss, their performance may be evaluated on a scale of economic utility values. A utility evaluation may be conducted with the aid of D. Bernoulli's Law of Diminishing Marginal Utility.[1]

The marginal utility law orginated in reflections by Bernoulli to the effect that the principle of maximizing the estimated economic gain could lead to unfavorable results in some cases. For example, if the possible loss for X is not small in relation to his fortune, he should not choose an even-money bet, although the principle of maximizing the estimated gain would recommend this. The reason, as Carnap[2] states, is that "the weight of a large loss should be more than proportional because X would suffer from a large loss disproportionately. If X has a fortune of 10,000, then he would suffer from a loss of 8,000 not only eight times as much as from a loss of 1,000, but much more because it would mean his near ruin. If X were to lose by ten successive accidents 1,000 each time, then every loss would hurt him more than the preceding ones, and the last would be the worst. Inversely, if X, with an initial fortune of zero, were to make ten or any other number of successive gains of 1,000 each, the satisfaction derived from subsequent gains would be smaller and smaller." Following the terminology of economists, the satisfaction conveyed by money or goods is measured by a number called its utility. Therefore, X's decisions must be guided by the principle of maximizing the utility of his gains rather than the gains themselves. Since, however, he cannot in general anticipate gains and utilities with certainty, he must apply the maximizing principle to the estimate of utility rather than to the unknown utility itself.

These ideas led Bernoulli to formulate the change in utility du with change in fortune df as

$$du = k\frac{df}{f}$$

where k is a constant which is characteristic of the person X at the time in question.

In general, since the fortune change cannot be known with certainty, i.e., it will be one of several possibilities with associated probabilities, the estimated utility of a fortune change only can be stated. Thus, suppose that f_0 is the initial fortune and that f can take on one of two values, f_1 or f_2, with probability q_1 or q_2, respectively. Then

---

Paper 58-1264, recommended by the AIEE Communication Theory Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1-6, 1959. Manuscript submitted January 3, 1958; made available for printing January 7, 1959.

L. S. Schwartz is with New York University, New York, N. Y.

$$u^{*1}=k(q_1 \log f_1+q_2 \log f_2-\log f_0) \tag{1}$$

where u^{*1} is the estimated utility value of the fortune change. Application of this idea to communication systems may take the form of assuming that an observer makes decisions with the aid of received information and that these decisions are rewarded or penalized. If the decisions are correct, his initial fortune is increased; if they are incorrect, it is decreased. The observer determines for himself the amount he gains or loses each time he makes a decision. If the decision is correct, the fortune following his decision is

$$f_1=(1+L)f_0 \tag{2}$$

where L is the percentage of his initial fortune invested in the decision. If the decision is incorrect, the fortune following the decision is

$$f_2=(1-L)f_0 \tag{3}$$

In these expressions gains and losses are given equal weight, but this is not necessary.

Assuming that the probability of correct decision is q and that of incorrect decision p and letting $q_1=q$, and $q_2=p$ in equation 1, the estimated utility of the fortune change becomes

$$\begin{aligned} u^{*1}&=k[q \log (1+L)f_0+p \log (1-L)f_0- \\ &\qquad \log f_0] \\ &=k[q \log (1+L)+p \log (1-L)] \end{aligned} \tag{4}$$

The value of L, which maximizes u^{*1} is

$$L=q-p,$$

so that

$$u^{*}=k[1+p \log p+q \log q] \tag{5}$$

which, except for the constant factor k, is the expression for the capacity of a symmetric binary communication channel of error probability $p(q=1-p)$.

Kelly[3] obtained the expression for the capacity of a symmetric binary communication channel by postulating a situation in which a gambler is receiving tips over a noisy communication channel. If the input symbols to the communication channel represent the outcomes of a chance event on which bets are available at odds consistent with their probabilities, the gambler can use the knowledge derived from the received symbols to cause his money to grow exponentially. The maximum exponential rate of growth of the gambler's capital is equal to the rate of transmission of information over the channel. Kelly's approach is suitable for the situation in which there is no limitation on the number of bets which can be placed and in which there is no requirement to maximize the reliability of betting. These limitations do not inhere in the utility value approach whose usefulness is demonstrated in the two following cases.

Case 1. Information Rate of Communication Systems

If repetition-integration is employed,

$$u^{*}=\frac{k}{(r+1)}[1+p \log p+q \log q] \tag{6}$$

with p a monotonically decreasing function of the integrations r. As $r \to \infty$, $q \to 1$, and $p \to 0$, and in the limit the entire initial fortune may be safely invested in each decision. However, the number of possible decisions varies inversely with the repetitions, and for an infinite number of integrations there are no decisions. Although the existence of a value of r which maximizes u^* might be expected, for Gaussian noise such a value does not exist because the quantity in the square brackets is a monotonically increasing function of r with maximum value of unity and with downward concavity. Hence u^* can only decrease with r. It appears, therefore, that instead of increasing the reliability of a communication channel by repetition-integration, one should simply invest that fraction of his initial fortune which corresponds with the reliability of the channel. In communication language this means that if time is unlimited, one should operate with maximum information rate. In this way the estimated utility is a maximum, a result consistent with the concept that the information rate is bounded by the capacity of the channel.

Case 2. Reliability of Radar Systems

To see the implication of the utility value concept to radar, it is useful to distinguish between certain characteristics of radar and communication systems. Communication is a co-operative enterprise between the transmitter and the receiver. Its chance nature derives from the presence of interference in the channel, originating from either natural or man-made causes. Radar, on the other hand, is essentially a measurement system in which observations are taken in an environment of noise. Because of the co-operative nature of communications, the receiver is directly penalized only if he makes a wrong decision concerning the transmitted signal. If he withholds decision until he is more confident, he makes fewer decisions and thereby reduces the possible gain which he might make by making more decisions. Only in this sense does he lose by waiting. In radar, on the other hand, the observer may lose equally by waiting or by deciding. If the target is an enemy bomber, it matters little whether the decision is that there is no target, or whether decision is withheld. Aside from losses which may be inflicted on enemy planes, the radar observer must be primarily concerned with safeguarding his initial fortune f_0. It may be lost by making a wrong decision or by failing to take one, either way.

Hence in the radar case the fortune following decision is either f_0 or βf_0, $0 \leq \beta \leq 1$, where β is a factor relating to the cost of a wrong decision, decreasing with increasing cost.

Thus,

$$f_1=f_0 \tag{7}$$

and

$$f_2=\beta f_0$$

so that the estimated utility is

$$\begin{aligned} u^{*}&=k[q_1 \log f_1+q_2 \log f_2-\log f_0] \\ &=[q_1 \log f_0+q_2 \log \beta f_0-\log f_0] \\ &=k[q_2 \log \beta] \\ &=k[p \log \beta] \end{aligned} \tag{8}$$

As $\beta \leq 1$, $u^* \leq 0$. For β small, u^* will be a correspondingly large negative number, indicating excessive loss. This can be avoided only by integration which reduces p, thereby increasing system reliability. In fact, as r, the number of integrations, becomes infinite, $p \to 0$. For radar $u^*_{\max}=0$. However, in practice u^* must be less than $u^*_{\max}$ because the number of integrations must remain finite. In fact, the number of integrations is limited by the data rate requirement, that is, by the time available for decision.

Thus, a radar system is not concerned with information rate, since its estimated utility is independent of information rate, increasing solely with system reliability.

Conclusion

The law of diminishing marginal utility can be applied not only to phenomena in the economic field, but also to those in the fields of communication and radar, a consequence of the fact that communications and radar involve decisions possessing an economic value measure. In the case of communication with no limitation on the number of decisions, i.e., on message duration, the criterion of performance is information rate because maximizing the information rate maximizes the estimated utility. In radar maximizing the reliability maximizes the estimated utility, consistent with data-rate requirements, and thus information rate is not a criterion of radar performance.

The 83B1 Teletypewriter Selective-Calling System

C. W. SMITH
ASSOCIATE MEMBER AIEE

C. J. VOTAW
NONMEMBER AIEE

A. L. WHITMAN
MEMBER AIEE

During the last decade and a half in particular, the use of teletypewriters on leased lines has grown very rapidly. The Bell System now has more than 50,000 such teletypewriter stations in service. In order to obtain the most communication for the least over-all cost, it is common practice, where the traffic load on the line will permit, to operate several stations on the same line. This results in a significant reduction in line cost compared with a line facility for each pair of stations. However, such multistation lines involve operating complications which somewhat offset the lower cost.

With several stations connected to the same party line without selecting equipment, all stations will receive all messages, and any sender must wait until the line is idle before he tries to send. An attempt at simultaneous sending may result in hopelessly garbled messages. Furthermore, even if a sender does wait until the line is idle, some other sender may also be waiting and both may attempt to send at about the same time.

In certain cases, circuit contention may not be a serious problem and a simple party line without station selection may serve in a satisfactory and economical manner. In many cases, however, such a simple party line would not be satisfactory. For example:

1. It may be desired to direct a message to one station, or a selected group of stations only. This may be done in order to obtain a certain degree of privacy, or more commonly, to obviate the necessity of checking all the traffic received at each station to select the messages intended for that station.

2. It may be important to eliminate contention for the opportunity to use the circuit. This contention can result in a certain amount of garbled copy which would require repetition, and additional lost time in coming to an agreement as to who is to use the circuit.

These points are especially important where the traffic load is high or where automatic tape sending is desired.

A selective-calling arrangement will direct messages to the particular stations for which they are intended. A number of types of selective-calling arrangements for use on teletypewriter circuits have been widely used. Various types of anticontention arrangements have been devised to prevent the confusion resulting from simultaneous attempts by two or more stations to send. The most successful of these is an automatic-transmitter-start arrangement. With this feature, the transmitter or keyboard at each station is under the control of one station on the line, the control station. The control station gives permission to each of the stations to send, in a predetermined order, by means of selective signals.

The *81*-type teletypewriter switching systems[1] provide these features for multistation full-duplex lines in a multiline system. These systems provide very complete means for automatic switching of messages together with alarms and elaborate means for supervising systems operation.

The *83B1* teletypewriter selective-calling system is intended to fill the need for a less elaborate and less costly system where station selection and the elimination of circuit contention are important. It is primarily adapted to systems consisting of a single-party line, but it may be used in multiline manual-tape-relay systems and also for automatic interline switching for a limited number of lines.

The *83B1* system combines the use of a particular type of station-selecting arrangement with an automatic transmitter-start feature. The most common station equipment includes an automatic sending and receiving (ASR) teletypewriter set, which includes, in addition to a teletypewriter for receiving and keyboard sending, a keyboard perforator for punching tape and a transmitter-distributor for sending from punched tape. Fig. 1 shows a *19ASR* set as installed at an *83B1* control station. The *19ASR* set was offered as an interim arrangement until a new ASR set in the *28* line (manufactured by the Teletype Corporation) became available, when some simplification of the *83B1* arrangements was possible.

The system also may be used with other teletypewriter equipment with some reduction in the features provided, or with the use of separate units to provide required features.

Station selection is obtained from the *28*-type stuntbox,[2] either in a printer or in a device called a sequence selector, which is a printer with the printing and paper-handling features removed, leaving only the selection features. In a printer the stuntbox provides means for operating various functions, or stunts, such as

figures shift (FIGS), letters shift (LTRS), carriage return (CR), and line feed (LF). In addition, the stuntbox can be arranged to:

1. Shift the typing unit into a nonprint condition upon the receipt of a suitable character combination, such as FIGS H LTRS.
2. Shift the typing unit back into the print condition upon the receipt of a selected character or combination of characters.
3. Open or close contacts upon the receipt of selected characters or character combinations. Such contact operation may be momentary, or the contacts may lock in the operated position and be released by a subsequent character combination.
4. Lock the stuntbox upon the receipt of an end-of-address or lock-out code, such as CR LF LTRS, so that no further selections may take place except for the shift to the nonprint condition and the release of all locked-in selections.

By these features, station selection is obtained to start transmitters individually and to call in one or more stations to receive a message.

In addition to the stuntbox, a station control circuit is provided at each station which functions in response to the operation of contacts in the stuntbox to control the starting of transmitters and the cutting on of receivers.

One transmitter-start circuit is provided for each multistation line. It is located at the control station. Its function is to start the transmitters at the various stations, one at a time, provided they have traffic to send. At manual keyboard stations without automatic tape transmitters, the attendant is alerted, provided she has indicated that she has traffic to send, and allotted a 10-second interval in which to start sending from the keyboard.

Features Provided

Figs. 2, 3, and 4 show typical *83B1* station arrangements in block diagram form.

The system provides features described in the following paragraphs.

Adaptation to Various Types of Teletypewriter Apparatus

The following teletypewriter apparatus may be used:

19ASR teletypewriter set

28ASR set

28 receiving only (RO) printer

28 keyboard sending and receiving (KSR) teletypewriter

14 typing reperforator and *14* transmitter-distributor

14 reperforator-transmitter (for interline switching)

Stations which are arranged to send automatically teletypewriter characters for selecting purposes without first having them punched in tape, are equipped with a *28*-type distributor. This distributor can be coded to send various letters by means of external circuits, but is not arranged to send from punched tape.

Tape Preparation and Format

At a station equipped for tape sending, the message is prepared in the form of punched tape. At the beginning of the tape, one or more call-directing codes

(CDC's) are punched. The CDC's are 2-letter codes. Each station is assigned a CDC to which it alone will respond. The CDC's of several stations may be inserted in the tape ahead of the message if it is intended for more than one station. To speed operation with multiaddress messages, predetermined group codes may be assigned for groups frequently called, as well as a broadcast code to include all stations on the line. After each CDC, an LTRS character is inserted. After all the address CDC's have been punched, the end-of-address, or lockout code, CR LF LTRS, is punched. This is followed by the text of the message and finally, the disconnect (end-of-message) code, FIGS H LTRS. A typical message format is shown in Fig. 5.

When the message tape is completed, it is torn off and inserted in the gate of the transmitter with the tight tape arm lowered. This is done whether the line is busy or not. The BID lamp lights. If desired, the station may be operated with continuous tape. In this case the end-of-message code of the first message must be followed immediately by the second message or by about 100 LTRS characters punched in the tape, so that there will be enough tape available to permit all of the first message to go through the transmitter head.

Transmitter Start

At the control station, the transmitter-start circuit functions to start the transmitters in order, provided they have traffic to send. This is done by sending transmitter-start codes (TSC) to each station. Each TSC is a 2-letter code like the CDC, but is distinguished from a CDC by the choice of the first letters.

The TSC's are stored in the transmitter-start equipment and sent one at a time in a predetermined order. When the station receives a TSC in its stuntbox and has no traffic to send, it transmits back to the control station the letter *V* as a no-traffic response.

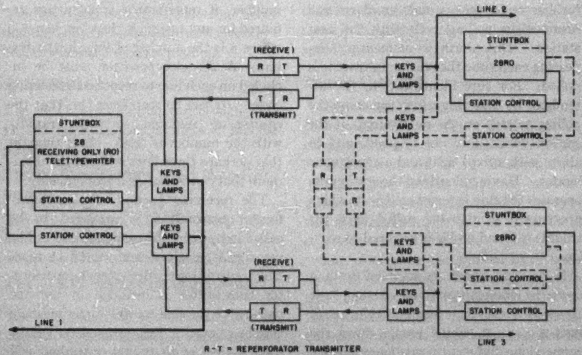
The receipt of this *V* at the control station is a signal to poll the next station. If a station has traffic to send, there is no *V* response. The transmitter starts automatically and sends the message.

After completion of a polling cycle the entire process is repeated. If desired, certain transmitters with anticipated heavier traffic may be polled more than once in a cycle.

Supervision of the polling operation is given to the attendant at the control station by providing a station lamp and a skip key for each station. A lighted lamp indicates that a station is being polled, or, if the lamp remains lighted, that the station is sending. The skip key allows the attendant to turn off the TSC for that particular station so that it is not polled while "on skip." This may be used when a station is taken out of service for maintenance, or, in connection with the polling patterns described hereafter, to control the flow of traffic from different stations.

Polling Patterns

The particular codes used for polling the stations should, in general, be of no interest to the customer and therefore may be selected for convenience in equipment arrangement. It has been thought that a number of specific arrangements would be particularly useful. The equipment may be modified by simple plug and cord changes for any of five arrangements designated polling patterns *A*, *B*, *C*, *D*, and *E* as follows:



R-T = REPERFORATOR TRANSMITTER

Fig. 4. Automatic relay station

```
(10 LTRS) AD LTRS AE LTRS BE LTRS BR LTRS
CR LF LTRS (MESSAGE TEXT) FIGS. H LTRS
(ADDITIONAL LTRS AS NEEDED FOR TEARING TAPE
OR FOR CONTINUOUS - TAPE OPERATION)
```

Fig. 5. Typical message format for multiple-address message

Polling Pattern *A*. This pattern can be used for a maximum of ten stations. Each station has one skip key and each station is polled four times for each revolution of the selector switch. More efficient use of the switch is the result.

Polling Pattern *B*. This is also intended for 10-station lines. Each station is polled four times per cycle and each station has two skip keys. Thus a station may be skipped entirely or twice out of four possible pollings.

Polling Pattern *C*. This pattern is for a maximum of 20 stations. Each station is polled twice in a revolution and each has one skip key.

Polling Pattern *D*. This pattern is also for a maximum of 20 stations. Each station is polled twice per revolution and has two skip keys.

Polling Pattern *E*. This pattern can be used for a maximum of 36 stations. Each station is polled only once per revolution, and has only one skip key.

If none of these specific patterns are satisfactory the selector can be wired to order for any desired pattern.

Priority Traffic

Urgent messages may be given priority so that they will be sent ahead of others. Each station has a priority button which, when pushed by the attendant, gives priority to the next message. Priority is obtained by a feature of the station-control circuit such that a transmitter with tape ready to send does not start until it has been polled twice unless its priority button has been pushed. Thus the polling cycle consists of two complete rounds of polling with the same TSC's, the first a search for priority traffic and the second a search for regular traffic. After every message sent, this pattern is repeated starting with the TSC for the next station in line. If no priority buttons have been pushed, no station starts on the first round of polling.

For types of operation where priority is not needed and the extra polling time is not justified, the priority option can be removed by a circuit strap at each station.

The sending of a priority message cancels the priority status of the station sending, so that if priority is wanted on a following message, the button must be pushed again. However, once a priority button has been pushed, the status is held until the message is sent from that station; it is not cancelled by the use of priority by another station which happens to get the first chance to start in the polling sequence.

Sending the Message

When a station having traffic to send is polled (the first or second time, depending on the priority status) the transmitter starts and sends first the CDC or CDC's which direct the message to the proper stations. At each called station, but at no others, the printer is unblinded (if in a *19ASR* set) or shifted into the print condition (if a *28* printer) on the receipt of the CDC. The sending of the CDC stops the transmitter at the sending station, which waits for a *V* answerback from the called station. This answerback is also the letter *V*, but its function differs from the *V* sent as a no-traffic response. This letter *V* now indicates that the printer at the called station is ready to receive a message. The arrival of the *V* at the sending station restarts the transmitter for the sending of the rest of the message.

After all of the CDC's have been sent, the end-of-address or lock-out code, CR LF LTRS, is sent. This code has two functions. It returns the carriage to the left and feeds out the paper so that the message text starts at the left side. In addition, it operates a mechanism in all of the stuntboxes on the line so that subsequent letter combinations in the text which are the same as CDC's, do not select any unwanted stations. Then follows the text of the message.

At the end of the text the disconnect signal, FIGS H LTRS, is sent from the tape. This disconnects all connected stations and causes the transmitter-start circuit to resume polling after a delay of about 300 milliseconds.

Keyboard Sending and Receiving Stations

At keyboard sending stations there is no automatic tape transmitter. Such stations are polled by sending TSC codes, however, like tape-sending stations. The station attendant indicates that there is traffic to send by pushing the KS (keyboard send) button on the control panel, which lights the BID lamp. This is equivalent to placing tape in the transmitter at a tape-sending station. When the station is polled, if the attendant has not made a bid, a *V* no-traffic response is sent back to the central office. If there is traffic to send, an LTRS character is sent back which simulates the start of sending and stops polling by the transmitter-start circuit. An audible alarm is sounded at the station, the station SEND lamp is lighted and the BID lamp goes out. These two signals tell the station attendant that she has 10 seconds to start sending. If there is no sending in 10 seconds, the transmitter-start circuit automatically will send FIGS H LTRS U and start a new polling cycle. The sending station will lose the opportunity to send, and must wait until the station is polled again. The same thing will happen if the attendant stops sending during a message for a period of 10 seconds.

Circuit Assurance

The *V* answerback response to a CDC, and the *V* no-traffic response to a TSC, constitute an effective circuit-assurance feature. Each time a TSC is sent to poll a station for traffic, either a *V* is returned indicating that the TSC has been received and there is no traffic to send, or the transmitter starts and sends the message that is waiting. In either case there is reasonable assurance that the line facility and the equipment are in operating condition. Likewise with the *V* answerback to a CDC, reception of the answerback is reasonable assurance of an operable circuit.

Timeout and Alarms

The system is provided with several features to prevent its automatic operation from being stopped by trouble affecting only part of it, such as one or more individual stations. These features cause an alarm to indicate the location of the trouble while operation of the rest of the system proceeds normally. Protection is given against failure of a response to a TSC, failure of a response to a CDC, and interruption of transmission from any cause.

If no response is received from a TSC, the transmitter-start circuit times out for 2 seconds, then sounds an alarm and resumes the polling cycle with the next station. This alarm is momentary, repeating each time the station in trouble is polled. For sure identification, the attendant, by throwing a key, can cause the polling to stop on the next round, at the station which does not respond, and to alarm with a fixed light and a continuous buzzer. Having identified the station she operates the skip key assigned to it, which prevents it from being polled until the trouble is found and it is restored to service.

If no answerback is received from a CDC, the transmitter-start circuit waits 10 seconds and then automatically sends FIGS H LTRS U, which breaks down the connections and conditions the circuit for a resumption of polling. At the sending station the red alarm lamp (AL) lights and the station transmitter cannot start again until the alarm is released. This warns the operator that she must examine the tape in the transmitter, correct the trouble if possible, and reset the tape to the beginning of the message before releasing the transmitter to start again.

If for any reason at all, the line remains idle and marking for a 10-second period, the same time out occurs and circuit operation, excluding the offending station, continues normally.

Manual Tape Relay

Any station on an *83B1* line may be used as a manual tape-relay station for relaying messages to and from another line. The *83B1* system then becomes a multiline system.

A typing reperforator, with or without an associated teletypewriter, is arranged to be called in by a suitably assigned CDC. The message for relaying to another line is received in punched tape. The tape is torn off and carried manually to the transmitter of the line for which it is intended and sent.

CDC's for stations on another line should be nonvalid for the line on which they were originally sent. For this reason, different sets of CDC's should be used on lines between which there is to be relaying of messages.

Automatic Interline Switching

Any station on an *83B1* line may also be used as an automatic interline switching point for the interchange of traffic with another similar line or with more than one line. The relaying of messages is accomplished by means of reperforator transmitters. Each line requires one reperforator transmitter for each line in the system other than itself. The total number of reperforator transmitters required for any system is therefore $n(n-1)$ where n is the number of lines in the system. A *28* teletypewriter must be included on each line to respond to selecting codes. It will be seen from this that the equipment required increases rapidly with the number of lines. It is thought that perhaps three lines is about the maximum that can be handled economically.

The receiving portion of each reperforator transmitter is arranged to be called in by a suitably assigned CDC. The message is received and stored in tape. The transmitter portion of each reperforator transmitter is included in the TSC pattern of the line to which the message is to be relayed. This transmitter will be started then in its proper order and will send the stored message.

Care must be taken in assigning CDC's where interline switching is provided. Codes assigned to stations on other lines should be nonvalid for the line on which they originate.

KEYS AND LAMPS

Lamp and audible signals are provided that indicate, both at the control point and at outlying stations, those conditions which need to be known to permit proper operation and adequate supervision of the traffic. Key switches are also provided to control circuit operations. Following is a list of the keys and lamps normally provided, with a brief statement of the function of each. The term key is used for a locking twist key, the term button for a nonlocking push button.

At the Control Station Only

The Station Lamp indicates which station is being polled or is sending.

The Station Skip Key controls the sending of individual TSC's.

The *V* Test and Stop Key control operation of the transmitter-start circuit.

The Alarm Transmitter Start Lamp (ALT) lights to indicate failure to receive a response from a polled station.

At All Stations (Including Control Station)

The BID Lamp lights to show that a bid to send has been made by inserting tape at an automatic sending station, or by pushing the KS (keyboard send) button at a keyboard station.

The KS Button conditions a station for keyboard sending when polled.

The SEND Lamp lights while the transmitter is running. At keyboard stations, it shows attendant when to send.

The MS (Manual Send) Button gives manual control of transmitter or of keyboard, without a wait for polling.

At All Stations

The PR (Priority) Lamp lights when the PR button is pushed to show a bid for priority.

The PR Button enters a bid for priority sending.

The ACO (Alarm Cutoff) Lamp when lighted indicates that the buzzer has been silenced by the AG (alarm guard) key.

The AG Key controls the alarm buzzer.

The AL Lamp (red) may be found at each station. When lighted, it indicates that the transmitter is locked out and will not start again until the alarm is released.

The AR (Alarm Release) Button puts out the alarm lamp and unlocks transmitter.

The MR (Monitor) Key permits the local typing unit to monitor or to print home copy automatically (with the *19ASR* set only).

PUSH-BUTTON SELECTION

Optional equipment is provided to permit station CDC's to be sent by operating push buttons instead of punching tape. If a message is to go to a number of stations, all of the required CDC's may be set up in the push-button circuit before the tape is inserted in the transmitter. They will then be sent, without further attention from the operator, ahead of the material in the tape, when the station next receives a proper poll. The CDC's, the same as those which would otherwise be punched in the tape, are generated by relays and a stepping selector and sent by an auxiliary cam-operated distributor driven by the motor of the typing unit or sequence selector.

Push-button selection may be provided at any station on an *83B1* system. Its use will result in a saving in time and a reduction in operator errors which might occur with manual punching of directing codes in the tape. It is especially valuable when manual tape-relay operation is desired, particularly for the relay point, where tapes without addresses may be received from other lines.

HALF- AND FULL-DUPLEX OPERATIONS

The *83B1* system is for half-duplex service only. A system for full-duplex operation is currently being designed.

SPEEDS

The system is capable of operating at 60, 75, or 100 words per minute, provided that the associated teletypewriter equipment is capable of operating at the same speed.

SYSTEM CAPACITY

On any one line the number of stations permissible will generally be limited within the capabilities of the system by the traffic generated and the speed of service required. The number of letter combinations for TSC's and CDC's which the system is designed to use sets an upper limit on the number of stations.

The circuits of the system have been designed to operate with 2-letter TSC's and CDC's. Also, in the interest of economy and simplicity in control circuits, certain limitations have been imposed on the choice of letter combinations.

Fig. 6. Outlying station with auxiliary receiving-only 28 printer

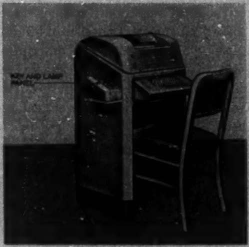


Fig. 7. Outlying keyboard sending and receiving station

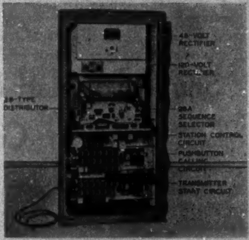

Fig. 8. Control station equipment cabinet

In general the letters *T*, in particular, *O*, and *M* are least desirable for selective-calling codes because, since each of these letters can be produced by a single open on the circuit, they could be produced falsely by hits on the line. The letter *H* is undesirable for a TSC or CDC since it is used in the disconnect code. The letter *V* is used for no-traffic response and answerback. The letter *Y* is not used in TSC's. This leaves 20 letters for TSC's. In the circuit design, the first letter of any TSC is restricted to either *Q* or *X*. The use of *Q* and *X* with each of the 20 letters as a second letter, including such combinations as *QQ*, etc., would result in 40 TSC's.

However, a restriction is imposed on the

TSC assignment by the system operation with CDC's. On any one *83B1* system, the first letter of all CDC's must be limited to one of two letters. It is the first letter of the CDC which stops the transmitter so that it waits for an answer back from a receiving station being called. To make it simpler for the system to distinguish between TSC's and CDC's, the two letters used for the first letter of the CDC's on a particular line may not also be used as the second letters of TSC's. As an illustration, if *A* and *B* are the first CDC letters for a line, *QA*, *QB*, *XA*, and *XB* cannot be used for TSC's on that line. Thus the total number of TSC's is reduced to 36, so that the total number of sending stations on a line is 36. This description applies to the standard wiring of the transmitter-start circuit and push-button circuit. The restriction is a practical, not a theoretical one. With changes in the strapping of the stepping selector, and with the use of *Y* or possibly the less desirable *T*, *O*, or *M*, the line capacity could be increased. However, it is expected that the demand for as many as 36 stations on such a system will be very small.

With CDC's, the letter *Y* need not be eliminated. So, with 21 second letters and two first letters, 42 different CDC's are available for a line where codes are sent from tape. Push-button codes are limited by the equipment to 20 second letters. *Y* is not used.

Station Equipment Arrangements

At *83B1* stations, in addition to the teletypewriters required, there are units of control equipment consisting of relays, stepping switches, electron tubes and associated equipment, together with power supplies, all mounted in apparatus cabinets. These apparatus cabinets can be located either in the same room with the teletypewriters or in an adjacent room as desired. Also fastened on the teletypewriter table, or *28*-type cabinet, are small metal cabinets in which are mounted the various signal lamps, control keys, and push buttons used in the operation of the system. Fig. 1 shows a typical control station equipped for a 20-station line and provided with push-button calling. The equipment includes the *19ASR* teletypewriter set, a 4-foot cabinet to house the sequence selector and the relay equipment, and the key and lamp cabinets shown mounted on the table.

Fig. 6 shows a typical outlying station with an auxiliary *28* RO teletypewriter. With this machine to print incoming copy, the *15* printer can be used to make copy while tape is being punched. At this station the control equipment is housed in the teletypewriter cabinet.

Fig. 7 shows a keyboard sending station with a *28*-KSR teletypewriter. Here also the control panel is mounted in the cabinet.

Fig. 8 shows the assembly of equipment in the cabinet for the control-station arrangement of Fig. 1.

The *83B1* system in expected to fill a growing need for improved teletypewriter service in cases where station selection on party lines, with the elimination of circuit contention, is important. The system has particular appeal because of its flexibility and its consequent capability of being adapted to many diverse uses.

Shunt-Coupled Magnetic-Amplifier Circuits

R. M. HUBBARD
ASSOCIATE MEMBER AIEE

A RECENT STUDY of magnetic-amplifier theory based on block-diagram techniques[1] suggested to this author that one potentially useful basic technique for extracting the output information from the simple self-saturating magnetic amplifier had been seriously neglected in the past. Although it is a well-recognized fact that the output information in a self-saturating magnetic amplifier is contained in the half-cycle average voltage across the gate winding, independent of power-supply variations, most of the conventional magnetic-amplifier circuits are so arranged as to make the output voltage proportional to the difference between the average gate voltage and the average supply voltage. (Subsequent to the preparation of this paper, Rosenstein published a description of a transactor[2] which bears a family resemblance to the shunt-coupled circuit described in this paper.) The afore-mentioned study of the theory revealed that some definite advantages could be derived by utilizing the average gate voltage directly as the output quantity. One obvious advantage, of course, results from the fact that this "output voltage" is thereby made independent of the regulation of the power-supply voltage. More important advantages, however, can be realized when the gate voltage is used to drive a subsequent stage of a multistage amplifier. It is shown later that the application of shunt coupling to a 2-stage magnetic amplifier effectively circumvents the traditional interstage coupling problems and yields an amplifier with all the advantages and few of the disadvantages of conventional 2-stage amplifiers.

Since, strictly speaking, shunt-coupled circuits do not represent a new class of magnetic amplifiers, all of the general statements relating to response time, voltage gain, driving-point impedance, etc., which apply to conventional self-saturating circuits also apply to shunt-coupled circuits. Shunt coupling is simply a method of utilizing conventional magnetic-amplifier circuits which is characterized by high signal efficiency, good stability, and circuitry simplicity.

Gate-Voltage Coupling

The basically simple method for coupling the gate voltage to a load may best be illustrated by reference to the simple half-wave magnetic-amplifier circuit of Fig. 1. During the indicated gating half-cycle if the voltage drop in the gate-winding resistance is sufficiently small, the half-cycle average-load voltage $\bar{e}_L$ will equal

---

Paper 59-635, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department. Manuscript submitted September 29, 1958; made available for printing March 9, 1959.

R. M. HUBBARD is with the Boeing Airplane Company, Seattle, Wash.

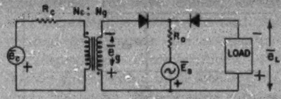

Fig. 1. Circuit diagram for the basic shunt-coupled magnetic amplifier

the half-cycle average-gate voltage $\bar{e}_g$. (Note that the diode-threshold-voltage drops tend to cancel.) The resistance R_0, which in a conventional circuit would be the load resistor, in the shunt-coupled circuit becomes merely a current-limiting resistor. Although the simple circuit of Fig. 1 is admittedly of limited practical value, merely exchanging efficiency for stability with changes in supply voltage and frequency, it forms the basis for several new circuits which represent distinct improvements over conventional circuits. It will be seen that the use of shunt coupling is most beneficial when the load is, in reality, a control winding on a separate core. This separate core may typically represent a subsequent stage of a multistage amplifier or it may be the complementary core in a full-wave amplifier.

A Solution to the Interstage Coupling Problem

Conventional techniques for coupling magnetic-amplifier stages in cascade are characterized by several deficiencies. For example, conventional full-wave stages in cascade, of necessity, employ power-wasting forcing-resistance to assure fast response in the second stage. Also, commonly, the highly peaked output-voltage waveform of the first stage leads to rectifier unblocking and associated problems in the second stage unless some interstage filtering is provided. This filtering, of course, lengthens the response time and adds to the complexity of the circuit. Ordinarily, the two stages are biased independently, a fact which does not contribute to good stability. Half-wave-type stages in cascade normally utilize more efficient coupling methods but they, as well as the full-wave circuits are sensitive to power-supply variations. Perhaps the most important limitation on the design of half-wave stages in cascade is imposed by the fact that the impedance presented by the control winding of the second stage must be small compared to the unsaturated impedance (excitation impedance) of the gate winding of the first stage. As has been indicated, shunt-coupling techniques effectively circumvent all of the afore-mentioned problems with the added bonus that the second stage, and any subsequent stage, of a multistage magnetic amplifier always inherently exhibits half-cycle response.

Consider the 2-stage half-wave shunt-coupled magnetic amplifier of Fig. 2(A), in which the two component saturable transformers are represented in the equivalent circuit form introduced by this author in an earlier paper.[1] As far as the equivalent circuit is concerned, it is sufficient to say that the nonlinear excitation impedance of each ideal saturable transformer is represented as a half-cycle average resistance $\bar{R}$ while the control-winding resistance and the gate-winding resistance are designated r_c and r_g respectively. All voltages are represented in terms of half-cycle average values and the polarities shown apply during the indicated half-cycle.

Good design practice dictates that the winding resistances r_{g1} and r_{c2} be negligibly small, with the result that the interstage coupling efficiency approaches 100% and the second-stage reset-voltage $\bar{e}_{r2}'$ is substantially equal to the first-stage gate voltage $\bar{e}_{g1}$. More specifically, under ideal conditions,

$$r_{g1}/R_0 \ll 1$$

$$r_{g1}/\bar{R}_2(N_{c2}/N_{g2})^2 \ll 1$$

$$r_{c2}/\bar{R}_2(N_{c2}/N_{g2})^2 \ll 1$$

and, as in the case of any conventional circuit,

$$R_0/\bar{R}_1 \ll 1$$

Although the foregoing assumptions greatly simplify the subsequent discussion of the shunt-coupled circuit, they are by no means essential to the good operation of the circuit. A more rigorous analysis, based on the afore-mentioned block-diagram techniques, in which the effects of winding resistance are included, is presented in the Appendix.

The fact that the second-stage reset voltage $\bar{e}_{r2}'$ is always substantially equal to the first-stage gate voltage $\bar{e}_{g1}$ means in effect that the operation of the second stage approaches that ideal condition associated with operation from a true voltage source. This type of operation is characterized by an over-all transfer characteristic which is substantially independent of nonlinearities in the excitation impedance of the second-stage core ($\bar{R}_2$). In effect, the second stage merely faithfully reproduces the first-stage output at a higher power level with an added half-cycle delay. The isolation provided by the blocking of diode D_2 during the second-stage gating half-cycle eliminates the gate-circuit loading which would ordinarily characterize operation from a low-impedance signal source. The presence of this same loading problem in the first stage, a Logan-type circuit, necessitates that the reflected control-circuit resistance be at least as large as the excitation impedance, that is

$$R_c(N_{g1}/N_{c1})^2 \geq \bar{R}_1$$

It is of interest to note here that the fact that the control-circuit resistance R_c must be appreciable to eliminate loading during the gating half-cycle is directly responsible for much of the nonlinearity introduced during the first-stage reset half-cycle. That is, if R_c could be negligibly small, its *I-R* drop caused by the finite nonlinear

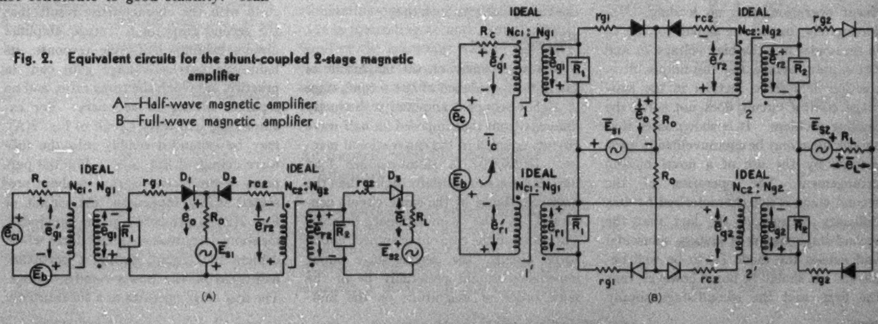

Fig. 2. Equivalent circuits for the shunt-coupled 2-stage magnetic amplifier

B—Full-wave a-c amplifier

C—Differential half-wave amplifier

excitation impedance $\bar{R}_1$ would be negligible and the first-stage gain would be linear and equal to the turns ratio (N_{g1}/N_{c1}). Thus, if a synchronous rectifier were to be added to the first-stage control circuit in the same manner that the rectifier D_2 operates in the second-stage control circuit, the resistance R_c could be made negligibly small compared to the input impedance, $\bar{R}_1/(N_{c1}/N_{g1})^2$. The resultant operation would be characterized by linear operation with no loading. Unfortunately, unless the signal voltage $\bar{e}_{c1}$ is sinusoidal like the bias voltage $\bar{E}_b$ and the supply voltage $\bar{E}_{s1}$, the simple introduction of a series rectifier in the first-stage control circuit does not solve the loading problem. It is shown later that this problem may be circumvented in some circuits by the use of a novel biasing arrangement. The operation of the second stage is not characterized by this difficulty because of the fact that the second-stage signal is always sinusoidal and causes the diode D_2 to be well behaved. It should be noted however, that the first- and the second-stage supply voltages must be properly proportioned to assure that diodes D_2 and D_3 operate properly. That is, during the second-stage reset half-cycle, the instantaneous value of $\bar{E}_{s2}$ must always exceed the instantaneous value of the reset voltage $\bar{e}_{r2}$ to keep D_3 blocked. Likewise, during the gating half-cycle, the instantaneous value of $\bar{E}_{s1}$ must exceed the instantaneous value of $\bar{e}_{r2}'$ to keep D_2 blocked. This condition is readily obtained by selecting the supply voltages such that

$$\bar{E}_{s2}/\bar{E}_{s1} \simeq N_{g2}/N_{c2}$$

The requirement on the magnitude of the input impedance of the second stage of a shunt-coupled amplifier is distinctly different from that imposed on half-wave circuits coupled in the conventional manner. Ordinarily, a shunt-coupled load impedance is substantially higher than the load impedance of the same circuit connected in the conventional manner. Therefore, in the case of the subject multistage circuit, the second-stage input impedance should preferably be of the same order of magnitude as the first-stage excitation impedance. That is,

$$\bar{R}_2(N_{c2}/N_{g2})^2 \approx \bar{R}_1$$

This is in marked contrast to the requirement on the conventional circuit that the second-stage input impedance be at least an order of magnitude smaller than the first-stage excitation impedance.

Therefore, it can be seen that the operation of the second stage of a shunt-coupled 2-stage circuit approaches that theoretical ideal limit which is normally so difficult to achieve in practice. That is, since rectifier unblocking during reset and loading during gating are substantially nonexistent, the half-cycle average voltage gain can be made substantially equal to the turns ratio. Further, the extremely close coupling between stages obviates the necessity for separate bias on the second stage thereby eliminating a source of stability and loading problems.

Representative Shunt-Coupled Circuits

Shunt coupling may be applied to all the conventional magnetic-amplifier circuits with the characteristic result that the second stage of a 2-stage amplifier always exhibits half-cycle response, its half-cycle average-voltage gain can, in practice, approach the turns ratio, and no separate biasing is necessary. For example, the half-wave circuit of Fig. 2(A) may be expanded readily into the full-wave circuit of Fig. 2(B). For the purposes of the block-diagram analysis presented in the Appendix, the circuit of Fig. 2(B) is presented in the previously mentioned equivalent circuit form which depicts the circuit during a particular half-cycle of the power-supply voltage. The first stage operates as a substantially

Vol.
Pt. 1
195

conventional full-wave doubler circuit with the exception that a split load (R_0) is used to eliminate the rectifier-unblocking-problem characteristic of the doubler circuit with a single load. Thus, characteristically, the first stage has slow response and low input impedance, is capable of high-voltage gain, has a linearity characteristic directly related to the nonlinearity of the excitation impedance $\bar{R}_1$, and in all other respects operates as a conventional full-wave circuit. However, the shunt-coupled second stage is characterized by somewhat different operating characteristics. The isolation between the control windings provided by shunt coupling eliminates the intrinsic, positive, voltage feedback[1] which is characteristic of series-connected control windings, with the net result that the second stage exhibits half-cycle response. Further, the second stage input impedance is simply the reflected excitation impedance and the average voltage gain is simply the turns ratio (N_{g2}/N_{c2}), as was the case, of course, with the previously described half-wave circuit. Possible variations of this circuit would involve such things as using a center-tapped circuit in the first stage to eliminate the need for two limiting resistors, or the use of that type of circuit in the second stage to obtain d-c output.

Shunt-coupling techniques applied to a particular type of 2-stage half-wave amplifier, namely one in which the outputs of both stages are delivered to a common load, yield an extremely versatile full-wave a-c or d-c output "universal" amplifier. The basic concept involved is functionally similar to that contained in the full-wave circuits developed by Lord[3] and by Barnhart[4] but the method of implementation is appreciably different.

Table I. Parts List for the Experimental 2-Stage Amplifier of Fig. 4(B)

D_1	HD 6007 silicon diode, 55 ma (milliampere) 150 volts
D_2	HD 6006 silicon diode, 75 ma, 70 volts
D_3	Automatic 1N440 silicon diode, 300 ma, 100 volts
E_{s1}	10 volts rms, 400 cps (cycles per second)
E_{s2}	57.5 volts rms, 400 cps
N_{c1}	750 turns, no. 36 HF*
N_{c2}	110 turns, no. 32 HF
N_{g1}	900 turns, no. 32 HF
N_{g2}	550 turns, no. 28 HF
R_b	10K ohms, 1/2 watt
R_{s1}	500 ohms, 1/2 watt
R_{s2}	200 ohms, 4 watts
Load	200 ohms
First-stage cores	0.625×0.75×0.25×1 mil Hymu 80
Second-stage cores	1.0×1.5×0.375×1 mil, Hymu 80

* Heavy Formvar

Consider the circuit diagram of Fig. 3(A) in which cores 1 and 2 are basic to the first stage, a conventional half-wave bridge circuit. Similar cores 3 and 4 constitute a shunt-coupled second stage which delivers an output to the common load during the first-stage reset half-cycle. Note that in order to produce a balanced full-wave output, the second stage must have unity voltage gain and therefore all windings on all cores must be identical, with the exception of N_{c1} and N_{c2}. For illustration purposes the circuit is biased in a manner which effectively circumvents the previously mentioned loading problem during the gating half-cycle. The voltage E_b operates the two rectifiers in the control circuit in synchronism with the power supply in order to isolate the input circuit during the gating half-cycle. The indicated circuit may be operated from a control-voltage source having effectively zero internal impedance. This novel bias circuit is functionally the same as one previously described by Schohan.[5] The configuration shown in Fig. 3(A) provides a reversible-phase full-wave a-c output, but the simple interchange of the connections at points *A* and *B* as indicated by the dotted lines changes the circuit to yield a reversible-polarity full-wave d-c output.

The circuit of Fig. 3(A) may be simplified appreciably by restricting its operation to that of a reversible-phase a-c output amplifier. Such a simplified circuit diagram appears in Fig. 3(B). Note that both gating and reset are achieved in the same windings on cores 3 and 4 and that one pair of rectifiers is necessary for resetting and one pair for gating. Note that for illustration purposes the bias circuit has been slightly modified to a configuration which produces less loading of the control-voltage source. The rectifiers are still effective in isolating the control circuit during gating. A possible further simplification of Figs. 3(A) and 3(B) could be achieved by using an isolated power supply for each stage and thus eliminating one pair of limiting resistors.

It is interesting to note that the passband of the preceding class of full-wave circuit is the average of the passband of a single-stage amplifier and that of a 2-stage amplifier.

An Experimental Shunt-Coupled Amplifier

The application of shunt coupling to a 2-stage differential half-wave type of magnetic amplifier is illustrated by the circuit diagram of Fig. 3(C). The first stage is basically a differential half-wave circuit with a split load while the second stage is a shunt-coupled half-wave bridge circuit. The first-stage bias is applied in the previously described manner which affords the same type of decoupling during the gating half-cycle as is inherently provided by shunt coupling. Two resistors R_b provide for bias adjustment and zero balance for the whole amplifier, since shunt coupling obviates the necessity for separately biasing the second stage.

The parts list and other specifications for the circuit of Fig. 3(C) appear in Table I and the experimental operation of the circuit is summarized by the results presented in Figs. 4(A), 4(B), and 5. The transfer curve of Fig. 4(A) gives a plot of the fundamental-frequency output voltage versus control voltage. The control-voltage source was a Variac which presented substantially zero internal impedance to the amplifier input terminals.

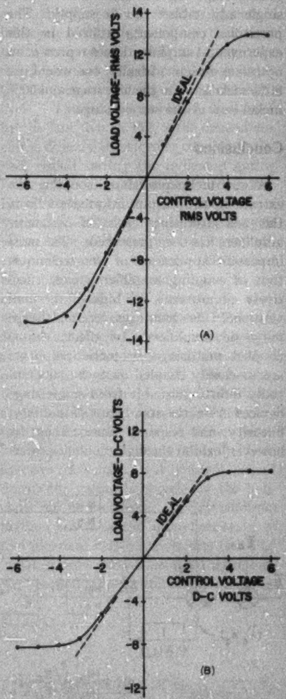

Fig. 4. Transfer curves for the experimental amplifier of Fig. 3(C)

A—A-c curves
B—D-c curves

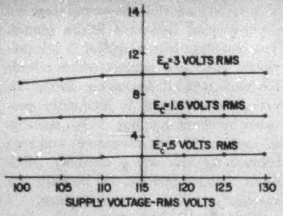

Fig. 5. Effect of power-supply regulation on the experimental amplifier of Fig. 3(C)

The transfer curve of Fig. 4(B) was obtained with a pure d-c control-voltage source also having substantially zero internal impedance. Fig. 5 illustrates the good stability of this circuit under conditions of changing power-supply voltage. Both the 10-volt supply for the first stage and the 57.5-volt supply for the second stage were transformed from the single adjustable 115-volt supply. The particular components utilized in this experimental amplifier do not represent an optimum design. Ideally, one would use 80% nickel-iron in the first stage and 50% nickel-iron in the second stage.

Conclusions

A new technique, shunt coupling, for extracting the output information from the self-saturating class of magnetic amplifiers has been presented. The most important application of this technique, that of coupling amplifier stages, effectively circumvents the bulk of the conventional disadvantages of multistage magnetic amplifiers. In effect, shunt-coupled multistage magnetic amplifiers are so closely coupled as to be substantially indistinguishable from single-stage devices from the standpoint of stability, linearity, and response time. They do, however, exhibit the high-dynamic power-gain characteristic of multistage amplifiers. This close coupling technique applied to 2-stage half-wave magnetic amplifiers, in which both stages operate into a common load, has been shown to yield an extremely simple, full-wave, a-c or d-c output universal amplifier.

It is hoped that this introduction of a basically simple new coupling concept will stimulate the re-examination of other conventional magnetic-amplifier circuits for the purpose of simplification or improvement in operating characteristics.

Appendix

Development of the Block Diagram

The circuit of Fig. 2(B) may be analyzed, without the necessity of employing the restrictive assumption that the winding resistances should be negligible, by making use of the block-diagram method of analysis.[1] Further, it is felt that the block-diagram method of analysis provides an insight into the mechanics of operation of the subject circuit type which is difficult to achieve by studying the circuit diagram alone.

The block-diagram method of analysis is based on the recognition that magnetic-amplifier operation can be described in terms of half-cycle average values and that conventional methods of circuit analysis (Kirchoff's laws, etc.) are usable when all voltages and currents are so expressed. Further, it must be recognized that the average voltage across a given winding over a complete cycle of resetting and subsequent gating must be zero and, therefore, if commutation effects are negligible, the magnitude of the half-cycle average voltage during reset must equal the magnitude of the half-cycle average voltage during gating. This fact may be expressed in Laplace notation as:

$$|\bar{e}_g(s)| = \epsilon^{-Ts}|\bar{e}_r(s)| \tag{1}$$

In the foregoing $\bar{e}_g(s)$ is the half-cycle average gate voltage, $\bar{e}_r(s)$ is the half-cycle average reset voltage, and T is time for one half-cycle of the power-supply voltage.

Write the loop equations for the circuit of Fig. 3 starting with the control circuit of the first stage and dropping the argument (s) for simplicity. During the indicated half-cycle

$$\bar{E}_b - \bar{e}_c + \bar{e}_{g1}' - \bar{i}_c R_c = \bar{e}_{r1}' \tag{2}$$

Since the rectifier associated with the resetting core $1'$ is blocked during the subject half-cycle, it can be seen that

$$\bar{i}_c = \bar{e}_{r1}'/\bar{R}_1(N_{c1}/N_{g1})^2 \tag{3}$$

For simplicity the reflected excitation impedance is designated as

$$\bar{R}_1(N_{c1}/N_{g1})^2 = \bar{R}_1' \tag{4}$$

Using equations 3 and 4 it can be seen that

$$\bar{i}_c R_c = \bar{e}_{r1}'[R_c/\bar{R}_1'] \tag{5}$$

Substituting equation 5 into 2 and combining terms yields

$$[\bar{E}_b - \bar{e}_c + \bar{e}_{g1}']\left[\frac{\bar{R}_1'}{\bar{R}_1' + R_c}\right] = \bar{e}_{r1}' \tag{6}$$

For simplicity of notation, let the first-stage intrinsic amplification factor be given by

$$A_{i1} = \frac{\bar{R}_1'}{R_c} = \frac{(N_{c1})^2/R_c}{(N_{g1})^2/\bar{R}_1} \tag{7}$$

Substituting equation 7 into 6 yields

$$[\bar{E}_b - \bar{e}_c + \bar{e}_{g1}']\left[\frac{1}{1+(1/A_{i1})}\right] = \bar{e}_{r1}' \tag{8}$$

Using equation 1 and noting that

$$\bar{e}_{r1} = \bar{e}_{r1}'(N_{g1}/N_{c1}) \tag{9}$$

it follows that

$$\bar{e}_{g1} = \epsilon^{-Ts}\bar{e}_{r1} = \epsilon^{-Ts}[\bar{e}_{r1}'(N_{g1}/N_{c1})] \tag{10}$$

Also,

$$\bar{e}_{g1}' = \bar{e}_{g1}(N_{c1}/N_{g1}) \tag{11}$$

Clearly, equations 8, 10, and 11 contain sufficient information to permit the construction of the block diagram for the first stage as shown in Fig. 6.

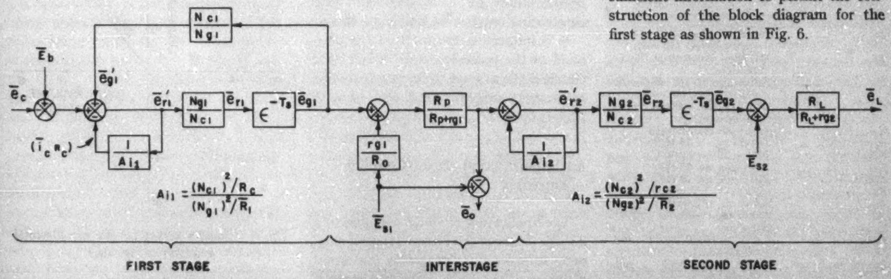

Fig. 6. Complete block diagram for the 2-stage full-wave amplifier of Fig. 2(B)

The equations for the operative interstage network associated with gating core 1 and resetting core 2 may be written directly from the equivalent circuit of Fig. 2(B) since, due to symmetry, the resultant equations are identical with those which would be written for cores 1′ and 2′ during the subsequent half-cycle. Thus, if the two loop currents are designated $\bar{i}_1$ and $\bar{i}_2$ and the reflected excitation impedance of core 2 is designated $\bar{R}_2'$, the two mesh equations may be written as follows:

$$\bar{i}_1(r_{g1}+R_0)+\bar{i}_2(R_0)=\bar{E}_{s1}-\bar{e}_{g1} \tag{12}$$

$$\bar{i}_1(R_0)+\bar{i}_2[R_0+r_{c2}+\bar{R}_2']=\bar{E}_{s1} \tag{13}$$

The simultaneous solution of the foregoing equations and the subsequent substitution of

$$\bar{e}_{r2}'=\bar{i}_2\bar{R}_2' \tag{14}$$

and

$$\bar{e}_0=(\bar{i}_1+\bar{i}_2)R_0 \tag{15}$$

yields

$$[\bar{e}_{g1}+\bar{E}_{s1}(r_{g1}/R_0)]\times\left[\frac{1}{1+r_{g1}[1/(R_0)+1/(r_{c2}+\bar{R}_2')]}\right]\times\left[\frac{\bar{R}_2'}{\bar{R}_2'+r_{c2}}\right]=\bar{e}_{r2}' \tag{16}$$

Also

$$[\bar{E}_{s1}-\bar{e}_0]\left[\frac{\bar{R}_2'}{\bar{R}_2'+r_{c2}}\right]=\bar{e}_{r2}' \tag{17}$$

or

$$\bar{E}_{s1}-\bar{e}_{r2}'\left[\frac{\bar{R}_2'+r_{c2}}{\bar{R}_2'}\right]=\bar{e}_0 \tag{18}$$

The foregoing expressions may be simplified by letting the gross load resistance seen by the first stage be designated R_p. Thus,

$$\frac{1}{R_p}=\frac{1}{R_0}+\frac{1}{r_{c2}+\bar{R}_2'} \tag{19}$$

Also the intrinsic amplification factor of the second-stage control circuit is given by

$$A_{i2}=\frac{\bar{R}}{r_{c2}}=\frac{(N_{c2})^2/r_{c2}}{(N_{g2})^2/\bar{R}_2} \tag{20}$$

Substituting equations 19 and 20 into 16 and 18 yields

$$[\bar{e}_{g1}+E_{s1}(r_{g1}/R_0)][R_p/(R_p+r_{g1})]\left[\frac{1}{1+(1/A_{i2})}\right]=\bar{e}_{r2}' \tag{21}$$

and

$$\bar{E}_{s1}-\bar{e}_{r2}'[1+(1/A_{i2})]=\bar{e}_0 \tag{22}$$

Equations 21 and 22 permit the construction of the block diagram for the interstage network and for the control circuit of the second stage.

Note that with relation to resetting core 2,

$$\bar{e}_{r2}'(N_{g2}/N_{c2})=\bar{e}_{r2} \tag{23}$$

and also from equation 1

$$\bar{e}_{g2}=\epsilon^{-T_s}\bar{e}_{r2} \tag{24}$$

which yields

$$\bar{e}_{g2}=\epsilon^{-T_s}[\bar{e}_{r2}'(N_{g2}/N_{c2})] \tag{25}$$

In the load circuit of the gating core 2′

$$[\bar{E}_{s2}-\bar{e}_{g2}]\left[\frac{R_L}{R_L+r_{g2}}\right]=\bar{e}_L \tag{26}$$

Equations 25 and 26 permit the completion of the block diagram for the second stage as shown in Fig. 6.

The symmetry of the full-wave circuit makes all of the foregoing equations valid for that half-cycle which was not explicitly treated in the equivalent circuit.

It can be seen from equations 16 and 18 that if

$$r_{g1}\ll R_0 \tag{27}$$

$$r_{g1}\ll \bar{R}_2' \tag{28}$$

and

$$r_{c2}\ll \bar{R}_2' \tag{29}$$

then the subject equations reduce respectively to

$$\bar{e}_{g1}=\bar{e}_{r2}' \tag{30}$$

and

$$E_s-\bar{e}_{r2}'=\bar{e}_0 \tag{31}$$

The resultant simplified block diagram appears in Fig. 7. This simplified block diagram is applicable to the introductory discussion which appears in the text.

Observations Based on the Half-Cycle Average Method of Analysis

In the author's opinion, the half-cycle average method of analysis in general and the block-diagram method of analysis in particular provide a fresh approach to the explanation of familiar phenomena associated with magnetic-amplifier circuitry. At the risk of excessive digression from the main topic of this paper, an effort is made herein to exploit the novel features of the subject methods of analysis in order to stimulate a re-examination of some of the classical methods of explaining magnetic-amplifier operation. It is suggested that reference be made both to the equivalent circuit of Fig 2(B) and to the block diagram of Fig. 6, while following the subsequent discussion.

The simple half-wave magnetic amplifier, as typified by the first stage of the circuit in Fig. 2(A), is the basic building block of which all conventional self-saturating amplifiers are constructed. Ideally, this simple amplifier can accept an input signal only during one (reset) half-cycle and can deliver an output only during the subsequent (gating) half-cycle of the power-supply voltage. The (shunt) input impedence during the reset half-cycle is simply the reflected excitation impedance $\bar{R}_1'$ and the response time in terms of half-cycle average values is one half-cycle pure delay of duration T. Aside from the fact that the maximum attainable output corresponds to only a half-cycle of the supply voltage, the simple half-wave circuit suffers from the deficiency that the control circuit loads the gate circuit during the gating half-cycle. This loading problem is illustrated by the fact that in Fig. 2 the control circuit is directly transformer coupled to the gate circuit during the indicated gating half-cycle. Thus the control circuit does in fact have an effect on the operation of the amplifier during the gating half-cycle rather than solely during the reset half-cycle. In order to minimize this loading effect, several courses are open to the circuit designer. For example, he may adjust the resistance in the control circuit R_c and/or the turns ratio to reflect a sufficiently high impedance from the control circuit into the gate circuit. Or, he may use a series inductor to raise the impedance of the control circuit without fear of affecting the response time. Another possibility, which is mentioned in the text, involves decoupling the control circuit during the gating half-cycle by the judicious use of rectifiers. A very common method involves the interconnection of two identical half-wave circuits (see Fig. 2(B)) in order to deliver a full-wave output as well as to eliminate loading by

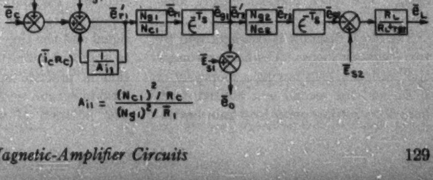

Fig. 7. Simplified block diagram for the circuit of Fig. 2(B) when the winding resistances are negligible

virtue of series-connected control windings. The simple act of series connecting the control windings of two simple half-wave amplifiers has such a profound effect on the operation of the amplifiers that a detailed study is warranted.

As a result of a holdover from the study of simple saturable-reactor circuits, the series connection of control windings in self-saturating circuits is often described as a phase-opposition connection which causes the induced voltages to buck. In reality, only the gating core is characterized by an induced voltage ($\bar{e}_{g1}'$). The resetting core reflects the necessary high impedance into the control circuit to eliminate loading in a manner somewhat analogous to the insertion of a series inductor in the control circuit of the simple half-wave circuit. The reflected impedance $\bar{R}'_1$ of the resetting core limits the average current in the control-circuit ($\bar{i}_c$) to the comparatively low excitation current. Of course, in some cases the resistance in the control circuit is of itself sufficient to eliminate loading, that is,

$$R_c/\bar{R}_1'>1 \text{ or } A_{fl}<1$$

This latter condition is often referred to as suppressed even-harmonic operation. Those former cases in which the control-circuit resistance R_c is small compared to $\bar{R}_1'$ are referred to as free even-harmonic operation.

It is clear that the fraction of the total voltage introduced into the control circuit which actually is effective in resetting the core is determined by the voltage division between R_c and $\bar{R}_1'$. This fact is clearly illustrated by equation 6. It is convenient to treat this voltage drop across R_c as a negative feedback voltage in the manner suggested by equations 5, 7, and 8, and as illustrated by the block diagram.

In the block diagram, the full-wave circuit is treated as an entity and the individual cores lose their separate identities over a complete cycle. Thus, during each half-cycle, one core is always resetting and one core is always gating and the circuit equations are independent of the particular half-cycle selected for study. Since the magnitude of the induced gate voltage $\bar{e}_{g1}'$ during the indicated half-cycle is equal to the magnitude that the reset voltage $\bar{e}_{r1}'$ had during the preceding half-cycle, it is clear that $\bar{e}_{g1}'$ is in reality a feedback voltage delayed by one half-cycle. The block diagram clearly illustrates this fact.

The block diagram is characterized by two feedback loops. The first is a negative feedback loop having a loop gain of $1/A_{fl}$ and the second is a positive feedback loop having unity loop gain but incorporating a pure delay. It is a simple matter to draw some general conclusions about the full-wave amplifier at this point. Note that the input voltage to the basic amplifier is the reset voltage $\bar{e}_{r1}'$ and the input impedance is the reflected excitation impedance $\bar{R}_1'$. The feedback voltage $\bar{e}_{g1}'$ introduced by the control winding of the gating core is directly in series with the input and serves to modify the impedance presented by the amplifier to the external signal source. In particular, the unity gain, positive, voltage-feedback loop lowers the effective input impedance to zero in the steady state. This explains the well-known fact that, in the steady state, the current in the control circuit is limited solely by the d-c resistance R_c and the amplifier can be described as current sensitive (or ampere-turns sensitive). This is clarified by noting that, in the steady state, the gate voltage during one half-cycle must equal the gate voltage during the subsequent half-cycle. Thus, during a given half-cycle, the gate voltage $\bar{e}_{g1}'$ must equal the reset voltage $\bar{e}_{r1}'$. It is therefore clear from the equivalent circuit and from the block diagram that a necessary condition or a steady state is

$$\bar{E}_b-\bar{e}_c=\bar{i}_cR_c$$

Although the magnetic amplifier is apparently current-sensitive in the steady state, it is most certainly voltage sensitive during transients because of the fact that the positive feedback is delayed. If this were not the case, it would be impossible to develop a voltage across the input terminals and thereby to achieve a change in reset voltage.

The negative feedback loop, which is not delayed, also has an important effect on the operation of the magnetic amplifier. In the absence of the subject loop, the unity gain positive feedback loop would cause the voltage gain of the magnetic amplifier to approach infinity. That is, if R_c went to zero, then $1/A_{fl}$ would go to zero and a steady state could not be achieved with any finite value of input voltage. Thus, the negative feedback loop lowers the voltage gain and provides stability.

It is of interest to investigate the source of the familiar magnetic-amplifier time constant by inspection of the block diagram. In the absence of negative feedback, the amplifier cannot achieve a steady state after the application of a signal and the time constant may be said to approach infinity. In fact, the operation in practice approaches that of an ideal integrator with an initial time delay. The addition of negative feedback by making R_c finite means that a steady state will ultimately be achieved. Thus a transient will ensue after the application of an input until the reset voltage has increased, by virtue of the positive feedback, to a level sufficient to provide the equilibrium negative feedback voltage. Note that if the negative feedback gain were unity, a steady state would be achieved in two half-cycles of duration T. If the negative feedback gain were to approach infinity, the positive feedback would be negated and the response time would be simply one half-cycle. This condition would obtain for very large values of R_c relative to $\bar{R}_1'$.

It should be apparent from the block diagram that, in the absence of the positive feedback loop, the response time would be simply one half-cycle (T) and the voltage gain could never exceed the turns ratio N_{g1}/N_{c1}. It also can be seen from the circuit diagram that, in the absence of the subject loop, the input impedance would be simply $\bar{R}_1'$. The elimination of the positive feedback loop is simply a matter of providing isolation between the two control windings. Shunt coupling does exactly this as evidenced by the second-stage block diagram. It is clear that the second stage is characterized by a half-cycle response time.

It can be seen from the block diagram of Fig. 6 that the voltage $\bar{e}_0$ across the limiting resistor R_0 has no direct effect on the second stage. However, the circuit is not completely insensitive to variations in the power supply $\bar{E}_{s1}$ unless the first-stage gate-winding resistance r_{g1} is small compared to the limiting resistor R_0. Further, the efficiency of the interstage is limited by the ratio of r_{g1} to the effective load on the first stage R_p. The control circuit efficiency of the second stage is limited by the ratio of the control-winding resistance r_{c1} to the reflected excitation impedance R_2'. Equations 27, 28, and 29 summarize the necessary conditions to make the coupling efficiency approach 100% and to cause the block diagram to simplify to that of Fig. 7.

Nomenclature

A_f=amplification factor
D=designates rectifying element
$\bar{E}_b$=average steady-state bias voltage
$\bar{e}_c$=half-cycle average control voltage
$\bar{e}_g$=half-cycle average gate voltage across gate winding
$\bar{e}_g'$=half-cycle average gate voltage referred to control winding
$\bar{e}_L$=half-cycle average load voltage (across R_L)
$\bar{e}_0$=half-cycle average voltage across current-limiting resistor R_0
$\bar{e}_r$=half-cycle average reset voltage across gate winding

$\bar{e}'_r$ = half-cycle average reset voltage referred to control winding
$\bar{E}_s$ = average rectified supply voltage
$\bar{I}_c$ = half-cycle average current in control winding
N_c = number of turns in control winding
N_g = number of turns in gate winding
$\bar{R}$ = average excitation impedance of saturable transformer referred to the gate winding
$\bar{R}'$ = average excitation impedance of saturable transformer referred to the control winding
R_b = total series resistance in bias circuit
R_c = total series resistance in control circuit
r_c = resistance of control (N_c) windings
r_g = resistance of gate winding
R_L = load resistance
R_o = current-limiting resistance
R_p = effective load resistance on first stage
s = complex frequency variable
T = time for one half-cycle of power-supply voltage
ϵ = base of natural logarithms

Coolant Instrumentation for Pressurized Water Reactor Power Plants

J. J. LIHOTA
MEMBER AIEE

C. B. HOPPA
MEMBER AIEE

NUCLEAR POWER has become a reality. The theory and classical experiments of half a century have been assembled and within the last decade have provided mankind with a new source of power. The problem of handling and controlling this new process is a monument in itself to technical ingenuity of the American engineer. At this stage of the art one cannot judge the nuclear power plant as a simple system, but with new technique and every day improvements this new industry will be established on an economical basis.

This paper deals with the instrumentation required of the medium cooling the reactor, and the facilities rendered by this instrumentation for control, indication, and safety.

Reactor Coolant Cycle

There are many processes that can be utilized for transforming the energy of the atom. For the purpose of this paper discussion will be limited to the pressurized water type of reactor system. A typical nuclear power plant main coolant system is shown in Fig. 1. In the interest of simplicity only one coolant loop is detailed; however, each of the number of loops connected would be physically and functionally identical.

The heat generated by the fuel in the reactor is transported by the coolant medium through the connecting piping to a heat exchanger wherein the energy is transferred to a second water system to be utilized as a steam source for the work load. It is necessary that a sufficient flow rate be maintained to prevent localized heating of the fuel elements. The main coolant pump returns the coolant water to the reactor for reheating. The system thus far discussed is a fluid water system.

An appendage to this system is connected to a pressurizer vessel wherein electric elements heat a relatively stagnant portion of the system water volume to a temperature and pressure sufficient to maintain the water volume in the circulating system in a fluid state. The steam blanket generated in the top of the pressurizer will also relieve the system of surges in water volume during operation.

From the foregoing it is obvious that pressure and temperature are two extremely important parameters in the design of a pressurized water reactor system. Likewise the accurate measurement of these two parameters becomes highly important in the safe operation of a pressurized water reactor system. The measurement of the temperature of the water as it leaves the reactor and as it enters the reactor is indicative of operating conditions within the reactor. The same applies to the measurement of system pressure.

Of a lesser degree of importance, but nevertheless important in the safe operation of the reactor power plant, is instrumentation for the following:

1. The pump head, in systems utilizing two speed pump control.
2. Coolant flow, in systems utilizing variable speed pump control.
3. Main loop stop valves position indication, either fully open or fully closed.
4. Pressurizer liquid level measurement.
5. Pressurizer temperature.

Modular Magnetic-Amplifier Instrumentation

An instrumentation system requires a parameter to be measured, a detector to transduce the physical change of the parameter into an electrical signal, and a receiver to utilize the signal for indication or control.

The detectors used to measure the plant parameters of fluid temperature, pressure, level, and flow are conventional. It is from the physical design aspects that these detectors become highly special. First the detectors must be designed so that all parts in contact with the fluid of the primary system are hermetically sealed either by welding or brazing. Second, the material used in the fabrication of the detectors must be specially selected. It must allow no matter to be introduced into the primary system which can become highly radioactive; and it must not become damaged by radiation. Third, because the detectors will be inaccessible for the extended periods of time that the reactor plant is critical, they must be designed for the highest degree of reliability and be relatively free of maintenance demands. Fourth, to provide the highest degree of plant protection the detectors must be designed to respond as rapidly as possible to changing plant conditions. Fifth, to provide for most efficient utilization of the reactor power

source the detectors must have the highest accuracy and reproducibility.

In addition to the aforementioned design criteria the detectors for reactor coolant instrumentation have been designed to be especially suited for use with the magnetic-amplifier type of circuits.

Temperature is measured by means of a resistance thermometer element inserted into the fluid; see Fig. 2(A). The element electrically forms one leg of a Wheatstone bridge circuit so that as the resistance of the element varies with temperature the resultant bridge unbalance becomes a function of temperature.

Pressure is measured by a bourdon tube type of detector as in a conventional pressure gage, Fig. 2(B). The tube tip is connected by suitable linkage to a movable core of a differential transformer. The motion of the tube tip with pressure is transferred to the movable core, which in turn varies the coupling between the primary winding and two secondary windings of the differential transformer. When the outputs of the two secondary windings are electrically subtracted, the net result is an electrical output which is a function of pressure.

Liquid level and flow are measured by the differential pressure type of detectors; see Fig. 2(C). For liquid level measurements the detector measures the difference in head between a reference column of liquid and the level of the liquid in ques-

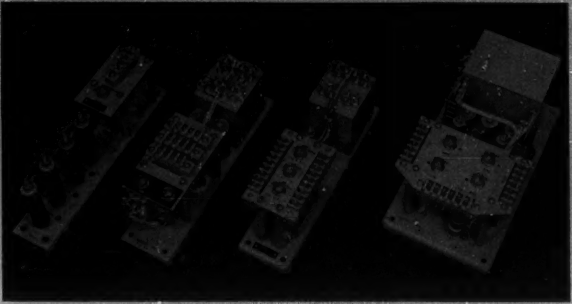

Fig. 3. Typical magnetic-amplifier modules (left to right, bridge, bistable controller, averaging amplifier, self-balancing amplifier)

tion. For flow measurements the detector measures the pressure drop across a venturi or an orifice plate. In either case the differential pressure acting on the bellows of the detector results in the motion of a movable core of a differential transformer. The position of the movable core is therefore a function of differential pressure. As in the pressure detector, for level measurements the movable core varies the coupling between the primary winding and secondary windings of a differential transformer, which results in an electrical output which is a function of level. In the case of flow measurements, because the pressure drop produced by the restriction is proportional to the flow squared, a specially designed differential transformer whose output is a square root function of head is used. As a result, for flow measurements the electrical output of the differential pressure flow detector is a linear function of flow.

The receivers vary in function but can be resolved to a few basic designs to fulfill most system requirements. In the heart of the reactor plant instrument, exists the magnetic amplifier. This device consists of windings on a core that exhibits rectangular hysteresis loop qualities and is inserted in the circuit between a power supply and the load to act as a variable impedance. The application of additional isolated windings and their proper excitation render the device as a controllable impedance with amplifying characteristics. The basic modules that are required for most instrumentation are: 1. bridge module, 2. demodulator module, 3. self-balancing amplifier module, 4. bistable controller module, and 5. summing amplifier module. A few of these typical modules are shown in Fig. 3.

The bridge module is used in temperature-measuring instruments to provide a voltage to the amplifier proportional to the temperature detected. The bridge is a Wheatstone circuit of which the detector resistive element constitutes one leg and which contains the necessary power supply and balance adjustments.

The demodulator module is applicable to detectors utilizing differential transformers as a signal source, rectifying the outputs of the secondaries, and determining the difference of their values to be presented to the amplifier as a single signal.

The amplifier module is a versatile circuit designed to utilize negative electric feedback for stability. Essentially it is a self-balancing magnetic amplifier which, because of the type of feedback employed, appears as a current source. The circuit possesses the advantage of eliminating drift, and nullifies the effects of frequency and voltage variation. Amplifiers of this type require a very low drain on the signal source during steady-state operation. The standard module is applicable as a wide-span or narrow-span amplifier and is adaptable to any of the previously discussed detectors by placing a bridge or demodulator module ahead of the amplifier. The output of this amplifier module is nominally zero to 20 milliamperes direct current. The accuracy for adverse conditions of voltage, frequency, and temperature is ±0.5%. The nonlinearity over the range is not measurable. The load regulation from 500 to 2,000 ohms is ±0.5%.

The bistable controller module (Fig. 4) is a self-saturating magnetic amplifier with positive feedback which provides a step change in output at a sharply defined and controllable setpoint. Control is provided to adjust the operating differential of this setpoint between input change limits of 1.0% to nominally 20% of span with extended ranges available. The set point is resolvable to within ±0.15% of input span and is accurate to within ±0.2% for adverse conditions of voltage, frequency, and temperature. Output for the tripped condition is nominally 320 milliamperes direct current at 28 volts.

The summing amplifier module is a simple saturable magnetic amplifier with

multiple control windings. Proper wiring connection to the input of the module permits addition and subtraction operations magnetically with circuit isolation as well as power amplification. The characteristics and output are comparable to the self-balancing amplifier already mentioned.

It is worth noting that the modules described are of the same general construction, and that their input and output characteristics are selected to provide matching units assembled into complete instruments.

Fig. 5 shows a simple diagram for a temperature instrument, and the first application of the modules into a complete instrument. A resistance thermometer detector has its element connected to the bridge module. The bridge-balancing rheostat nulls the output voltage E_G at maximum temperature, providing the best accuracy in the operating span and providing an output inversely proportional to temperature. The output voltage is rather weak for control application and a self-balancing amplifier module is utilized to strengthen the control signal and apply it to the controllers. The single amplifier can provide either wide-span or narrow-span operation. Where it is desirable to have both, a second amplifier module is paralleled in the circuit fulfilling the requirements.

Instruments in applications where a differential transformer transduces the parameter measurement (pressure, level, and flow) utilize the modules outlined for the temperature instrument except that the bridge module is replaced by a demodulator module; see Fig. 6. Again, service can be provided for wide-span or narrow-span, and for wide- and narrow-span operation.

A typical computer channel provides for shutdown of the reactor for any one of a number of dangerous parameter conditions in the system. A master shutdown bistable module (Fig. 7) similar to the previously described bistable controller module, but with a larger output capacity, is utilized. An auctioneer module monitors the outputs of several shutdown parameter bistables in various measuring channels. The control and bias windings are connected circuitwise to maintain full output for no control signal in. When a dangerous parameter condition is detected, the parameter bistable controller will "turn on" delivering full output via the auctioneering diode to the master shutdown bistable control winding. A single control signal such as this will "turn off" the master shutdown bistable and its output will be reduced to a value near zero established by the quiescent value of its core. The output normally energizes a solenoid latch in the rod mechanism. In "turning off" the solenoid is de-energized and the control rods are quickly inserted into the reactor core.

The aforementioned computer is a simple decision-making device. A second type of computer continuously monitors several parameter signals, determining the error in their relationship and initiating corrective action for the error. A typical example is found in the T-average (T_{avg}) controller. The relationship to be maintained for a steady power condition is expressed by the equation

$$T_h + K_1 \frac{dTh}{dt} - K_2 F_S - T_{\text{reference}} = 0$$

where

T_h = reactor outlet temperature
K_1 = adjustable constant in units of time
F_S = steam flow in per cent of full flow
K_2 = adjustable constant for converting steam flow to equivalent degrees Fahrenheit
T_{ref} = adjustable operating reference for T_{avg}

Fig. 8 represents a typical block diagram for this computer.

Normally T_h and T_c (reactor inlet temperature) diverge linearly and proportionally from the T_{avg} for the full range of power. Having established the value of T_h over this range, the T_h parameter channel supplies one control input to the

computer. An amplifier module extracts the derivative of the T_h signal (effective only during power changes) and supplies this signal to a summing amplifier module where it is combined with the T_h signal to provide the complete temperature expression at any instant for the foregoing equation. The temperature expression is transmitted to a second summing module where it is combined with the reference signal and the signal representative of the steam flow in a subtractive direction to provide the error signal. The error signal is passed on to two bistable controller modules where for a preset positive error the bistable designated RODS IN will initiate a slow insertion of the control rods until the error becomes zero, or for a negative error RODS OUT will be initiated for proper corrective action.

Instrumentating the Reactor Coolant System

From Fig. 1 it will be noted that temperature detectors are located in the main coolant loops to measure T_h and reactor inlet temperature T_c. The detectors are located on the heat exchanger side of the loop isolation valves for plant reliability considerations. In reactor plants of more than two loops, temperature detectors are also located in the steam generator T_{SG}.

The temperature measurements are utilized as follows:

1. The measurements provide a direct measurement of the temperature of the fluid. Wide-range (WR) temperature measurements, from cold start up to plant-operating temperature, are used to provide indication during plant start-up. Narrow-range (NR) temperature measurements made in the normal operating range of the plant are used for indication, and for reactor safety considerations, to provide automatic cutback of reactor power in the event of high T_h.

2. In reactor plants of more than two loops the NR T_h and NR T_c measurements may be auctioneered and the highest T_h and T_c measurements utilized for computing reactor T_{avg} for indication and reactor automatic control. Here also the auctioneered highest T_h measurement may be utilized to provide for automatic cutback of reactor power. Likewise the WR T_c measurements may be auctioneered and compared with individual T_{SG} to prevent accidentally starting up a coolant pump of a shutdown loop and pumping cold water into the reactor. The cold water, serving as a better moderator than the normally hotter water, could cause excessive reactivity sufficient to damage the core.

Pressure measurements are normally made in the pressurizer and in each of the main loops, as shown in Fig. 1.

The pressurizer pressure measurement is utilized for indication, for control of the pressurizer heaters, and for alarm and reactor protection. The loop pressure measurements are utilized as backups for the pressurizer pressure measurement to provide alarms and reactor protection. The loop pressure detectors are also used for indication only when bringing an isolated loop up to pressure and back on the line. With a loop isolated and depressurized for maintenance it is necessary to refill and bleed the loop and then pressurize it to reduce loading on the gate of the loop valve in order to open a valve and reconnect the loop to the reactor system.

Main loop stop valves during normal plant operation are fully open to permit free flow of coolant. A valve in anything other than the fully open position would restrict the coolant flow through the reactor and would result in excessive temperatures within the reactor.

Main loop stop valves are provided, however, to permit deliberate isolation of a loop from the reactor for loop maintenance purposes or simply to stop the flow of coolant through a loop of a multiloop plant in the event that power requirements are such as to not warrant operating the loop. For either of these latter two cases valves or a valve in anything other than the fully closed position would not be serving its intended purpose. Valve position indications, therefore, either fully open or fully closed, are utilized in reactor safety circuits or coolant pump interlock circuits.

In reactor systems utilizing variable speed pump control, coolant flow is usually varied as a function of reactor power in order to conserve the energy required to drive the pumps. In this type of operation excessive coolant flow simply means insufficient utilization of power. However, insufficient coolant flow means more transport time for coolant to flow through the reactor. This being the case, the coolant will become hotter and could conceivably boil into steam, which in turn could result in damage to the reactor. Coolant flow in the individual loops is therefore measured, totalized, and compared with a reactor power level measurement (neutron level), to provide alarm and core protection in the event that an unsafe power to flow ratio exists.

As stated previously, the pressurized water reactor system is a solid water system except for the pressurizer. Since the pressurizer serves a two-fold purpose: 1. of heating water to generate steam for maintaining pressure on the coolant system, and 2. as a surge tank to take care of the expansion and contraction of water in main coolant system due to changes in average coolant temperature, it is necessary for the operator to maintain the level of water in the pressurizer within upper and lower limits in order that the pressurizer may perform properly under normal plant-operating conditions. A measurement of pressurizer liquid level is therefore made to give the operator an indication of level and to provide alarms and heater power cutoff protection.

The pressurizer temperature measurement serves as cross reference on pressurizer pressure measurement and also as a backup for the pressurizer liquid level heater power cutoff protection. The temperature detector is located just above the uppermost heating element in the pressurizer. Should liquid level become lower than the heaters and the level heater power cutoff protection fail to take appropriate action, the heaters heating the steam will superheat the steam. When the measured temperature approaches unsafe limits, an alarm and heater power cutoff protection control action is initiated.

Conclusions

The outstanding advantage of a nuclear power plant is the ability to operate for extended periods without refueling. Essentially this means power for remote areas and locations presently undeveloped for lack of utility power. Providing power facilities to the areas bares the need for plants of low cost, reliability and freedom from maintenance, and economical operation. Hand in hand with these requirements, reliable and accurate instrumentation can provide a major step toward plant simplification and efficiency. Magnetic-amplifier instruments inherently exhibit the following advantages:

1. They are rugged. Being static devices magnetic amplifiers are less susceptible to adverse environmental conditions. They require no maintenance and the life of these units is equal to the life of the plant itself.
2. They are efficient. The low internal losses are limited to rectifier forward resistance and winding resistance.
3. They have stability. The characteristics of operation are predictable and repeatable within close tolerances, the limiting factor being the aging process of rectifiers. Proper rating selection of the rectifiers minimizes this process. Proper design of temperature-compensating circuits minimize effects of ambient temperature changes. These devices have a high signal-to-noise ratio.

The magnetic amplifier compares favorably with other systems of instrumentation for amplification. However, it offers a lower frequency response and provides a highly distorted output compared to some systems. The effect of these drawbacks is offset in this application where plant parameter changes are relatively slow and, the distortion being predictable, its effects can be cancelled out in alignment and calibration.

The utilization of building-block modules to assemble an instrument channel lends itself to modern production. The flexibility of these modules provides an infinite variety of control and computation functions.

It is because of these requirements that the magnetic amplifier has become a new member of the family of instrument systems. This addition is a natural choice in the nuclear power plant field, regardless of the process utilized.

On the Feedback in Magnetic Amplifiers

II—Combined Magnetic and Electric Feedbacks

L. A. FINZI
MEMBER AIEE

J. J. SUOZZI
ASSOCIATE MEMBER AIEE

A PREVIOUS PAPER[1] has presented a steady-state and transient analysis of various types of feedback, magnetic or electric, applied to a self-saturating bridge or center-tap amplifier. This paper is a brief extension of that treatment to certain combinations of a positive magnetic feedback and a negative electric feedback as used by Geyger in "voltage-balance" and "current-balance" potentiometer-type amplifier circuits.[2-4] The essential principle of these feedback combinations is well-known: The positive magnetic feedback reduces the control winding current, while the negative electric feedback insures stability and linearity without modifying the current requirements of the control winding. Two examples are shown in the schematics of Appendixes I and II. (The symbols and terminology are those used consistently in reference 1 and shall not be restated in detail.)

Steady-State Behavior

Voltage-Balance Circuits

In Appendix I, a positive magnetic load-current feedback is associated with a negative series electric load-current feedback. The network analysis is straightforward; the voltage equations of the various loops and the magnetomotive force (mmf) expressions of the cores are written using half-cyclic averages as the variables and relating the preset flux level φ_p to the half-cyclic average mmf F_p of all currents acting on the resetting core by means of an empirical "core-control" curve $\varphi_p=f(F_p)$. Appendix I presents the expressions of the gross voltage gain K_E, of the current gain K_A, of the input resistance R_i, and of the output resistance R_0 and generator gain $\mathcal{K}$ of the Thevenin equivalent of the output circuit. The expressions are given in terms of the voltage gain K_E^* of the "basic" bridge amplifier without feedbacks. Certain approximations suggested by the relative order of magnitude of the parameters in usual designs, are stated in the Appendixes. It should be noted that the current gain K_A depends solely on the magnetic feedback applied, and that the voltage gain K_E can be varied independently without appreciably affecting K_A.

The general expressions simplify if the self-balancing condition $(1-\beta_m K_E^*)=0$ is imposed. In this case the current gain K_A, and thus also the input resistance R_i and the volt-ampere gain $K_{EA}=K_E(K_A)$, become equal to infinity. The further addition of a suitable bias establishes a type of operation in which the input current $I_i=I_c$, is zero over the range of control, while the output remains dictated uniquely by the control voltage E_c with the voltage gain $K_E=1/\beta_c=R_0/r_{sc}$.

(It is recognized that the instantaneous feedback mmf $N_f i_f$, which has the waveform of the output current i_L added to the constant mmf of the bias, may not match the waveform of the instantaneous mmf required by the resetting core. Hence, instantaneous currents i_c flow even when their half-cycle average I_c is zero. Nevertheless, the zeroing of the average control current in itself remains a very interesting feature.)

Paper 58-1232, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Pittsburgh, Pa., October 26–31, 1958, and re-presented at the Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted July 14, 1958; made available for printing December 4, 1958.

This work was performed at the Carnegie Institute of Technology under the sponsorship of the Minneapolis-Honeywell Regulator Company, Brown Instruments Division of Philadelphia, Pa. Parts of this paper are abstracted from a doctoral dissertation by J. J. Suozzi. The authors also wish to acknowledge the friendly suggestions given by W. A. Geyger in informal conversations.

Vol.
Pt. 1
1959

Practically a perfect self-balancing may not be obtained over any broad range. The core-control curve is not a straight line (nor, really, is it a sufficiently accurate criterion in this critical question of "zeroing"); also the conducting rectifiers are not the "constant resistors" assumed in the analysis. Hence the theoretical condition $(1-\beta_m K_E^*)=0$ may not be met consistently, and certain values of I_c, positive or negative at various outputs, remain associated with the amplifier control. The band of these values, however, can be quite narrow, and thus the amplifier, in terms of half-cyclic values, can be compared to an almost "ideal voltmeter." It may be noted that the value of the control circuit resistance R_c has no influence on the operation if $(1-\beta_m K_E^*)$ is zero, but actually the practical departures from zero set an upper limit to the admissible value of R_c in the steady state. The general expression of K_E given in Appendix I, can be rewritten as:

$$K_E=\frac{2fN_gK_\varphi N_c}{[R_c+r_{s2}(1-{}^{r_{s2}}/R_g)][1-\beta_m K_E^*]+\dfrac{r_{s2}}{R_g}2fN_gK_\varphi N_c} \qquad (1)$$

where $(1-\beta_m K_E^*)=\left(1-\dfrac{N_f}{R_f}\dfrac{r_{s1}}{R_g}2fN_gK_\varphi\right)$ does not depend on R_c. For large values of R_c with $(1-\beta_m K_E^*)=\delta\neq 0$, the first term in the denominator of equation 1 can intervene to modify significantly the gain K_E. Since δ varies at various outputs, this results in a loss of linearity. In particular, for negative values of δ, the gain K_E may become infinite or negative, i.e., the amplifier is unstable at certain outputs with large R_c. Other limitations on the value of R_c arise in the matter of transient response, as shall be seen.

CURRENT-BALANCE CIRCUITS

In Appendix II, a positive magnetic load-current feedback is associated with a negative shunt electric load-current feedback. Again the steady-state gains and input and output impedances are given in terms of the basic amplifier gain K_E^* (evaluated with a control circuit resistance $R_c=R_K+2r_c$). Since the electric feedback is applied in shunt with the terminals of the control circuit winding, this circuit differs considerably from that of Appendix I. For instance, here, the voltage gain K_E, and the current gain K_A both vary with changes of the electric feedback. The essential feature of this circuit is that the input resistance $R_i=dE_c/dI_i$ is less than the sum of R_K and $2r_c$.

The general results simplify if the further condition $(1-\beta_m K_E^*)=0$ is imposed. In this case, again the half-cyclic control winding current can be zeroed over the range of operation, if a proper bias is added, and thus the voltage at the control winding terminals is also zero in terms of half-cyclic averages, regardless of the value of the control winding resistance, $2r_c$. In other words, the input resistance R_i reduces simply to $R_i=R_K$, and one can say that the winding resistance $2r_c$ is not seen from the control source. Practical departures of $(1-\beta_m K_E^*)$ from zero may be unavoidable over the range, but the band of actual values of I_c and of the winding terminal voltage $E_T=2r_cI_c$, can be quite narrow; thus the amplifier, viewed from the control winding terminals, $(x-x)$ can be compared to an almost "ideal ammeter." (In this case, the general expression given for K_E shows that the actual departures of $(1-\beta_m K_E^*)$ from zero practically set an upper limit on $2r$, and/or a lower limit to R_K, in terms of linearity and steady-state stability.)

Magnetic and electric feedback combinations, essentially similar to those considered in Appendixes I and II, can be obtained using the load voltage, rather than the load current, to provide either feedback or both. The main difference is in the value of output resistance R_0 that results. Generally the effect of the negative electric feedback on the output resistance dominates; hence R_0 is increased above the output resistance of the basic amplifier, if an electric load-current feedback is used, and is decreased by the use of an electric load-voltage feedback.

Transient Behavior

The self-balancing action described for the steady state is disrupted during transients. The matter of transient response is treated in the following with the same methods used in reference 1 and the temporary disturbances that intervene in the transient are related to the amplifier time constant.

VOLTAGE-BALANCE CIRCUIT

The circuit of Appendix I is considered again, first in general terms and then with the additional self-balancing condition $(1-\beta_m K_E^*)=0$. In general terms, assuming that the slope of the core-control curve K_φ, and thus the basic amplifier gain K_E^*, are constant over the range of outputs covered in the transient, and that the bias is supplied from a current source, the difference equations (with n = a positive integer) are:

$$E_{c(n)}=R_cI_{c(n)}+r_{s2}(I_{L(n)}+I_{c(n)})+2fN_c(\varphi_{p(n)}-\varphi_{p(n-1)}) \qquad (2)$$

$$E_{g(n)}=2fN_g(\varphi_s-\varphi_{p(n-1)})+R_gI_{L(n)}-r_{s1}I_{f(n)}+r_{s2}I_{c(n)} \qquad (3)$$

$$r_{s1}(I_{L(n)}-I_{f(n)})=R_fI_{f(n)}+2fN_f(\varphi_{p(n)}-\varphi_{p(n-1)}) \qquad (4)$$

$$N_fI_{f(n)}+N_cI_{c(n)}+{}_{\text{bias}}=\frac{\varphi_{p(n)}-\varphi_K}{K_\varphi} \qquad (5)$$

φ_K is the intercept of the linearized core-control curve with the φ_p axis; $\varphi_{p(n)}$ is the preset flux level at the end of the nth half-cycle while the voltages and currents are half-cyclic averages of the nth half-cycle. For a constant gate voltage E_g, considering only increments from some initial steady state, and assuming that the control voltage E_c is applied at the beginning of a half-cycle and remains constant thereafter, equation 2 becomes:

$$\zeta E_c=\varphi_{p(n)}-\alpha\varphi_{p(n-1)} \qquad (6)$$

where

$$\zeta=\frac{K_\varphi\dfrac{R_c}{N_c}}{1+v+K_{EN}^*(1-q)}$$

and α, q, and v are given in the Appendix I. Equation 6 has the same form found in all cases of the analysis of reference 1 and its solution is

$$\varphi_{p(n)}=\zeta E_c\left(\frac{1-\alpha^n}{1-\alpha}\right) \qquad (7)$$

A continuous "modular" function $y(t)$ can be determined, which for $t=n\pi/\omega$ $(n=0,\ 1,\ 2,\ 3\ \ldots)$ satisfies the condition $y(t)=\varphi_{p(n)}$. This function for $0\leq\alpha<1$ is an exponential characterized by the time constant,

$$\tau_y=\frac{\pi}{\omega}\,\frac{1}{ln\ 1/\alpha}$$

and

$$\varphi_{p(n)}=\frac{\zeta E_c}{1-\alpha}(1-e^{-\pi n/\omega\tau_y}) \qquad (8)$$

Appendix I also presents an expression for the approximate time constant τ_a of the familiar slow-transient approach, in which the discrete values of the half-cyclic average currents and of the preset flux are substituted with continuous time functions. This time constant is adequate for transients requiring many cycles. If the delaying effect of the feedback-loop coupling is neglected (i.e. $N_f^2/R_f\ll N_c^2/R_c$), τ_a simplifies to the familiar form

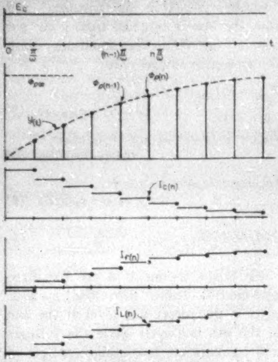

Fig. 1. Transient of preset flux φ_p, control current I_c, feedback current I_f, and load current I_L for a self-balancing amplifier of the voltage-balance type

$$\tau_a=\frac{1}{2f}K_E\frac{N_c}{N_g}$$

in which the voltage bandwidth-gain product is unchanged by the feedback, and the dynamic power gain is given by $D_p=2fK_AN_g/N_c$. The limitations of the approximate approach have been mentioned in section III of reference 1 and shall be re-examined later in this paper.

In perfect self-balancing, the control current $I_{c(n)}$ obtained by solving equations 2, 3, and 4 simultaneously with the condition $(1-\beta_mK_E^*)=0$ is

$$I_{c(n)}=\frac{1}{K_\varphi N_c}\left(1+\frac{N_f^2}{N_c^2}\frac{R_c}{R_f}K_{EN}^*\right)\times (\varphi_{p(n)}-\varphi_{p(n-1)}) \quad (9)$$

while the load current $I_{L(n)}$, and the feedback current $I_{f(n)}$ are respectively

$$I_{L(n)}=-2f\frac{N_f}{R_f}\frac{r_{s1}}{R_g}(\varphi_{p(n)}-\varphi_{p(n-1)})-\frac{r_{s2}}{R_g}I_{c(n)}+\frac{2fN_g}{R_g}\varphi_{p(n-1)} \quad (10)$$

$$I_{f(n)}=\frac{-2fN_f}{(R_f+r_{s1})}(\varphi_{p(n)}-\varphi_{p(n-1)})+\frac{r_{s1}}{(R_f+r_{s1})}I_{L(n)} \quad (11)$$

The simplifications that result for the expressions of α and of τ_a with the self-balancing condition $(1-\beta_mK_E^*)=0$, are seen in Appendix I.

Fig. 1 shows plots of φ_p, I_c, I_L, and I_f in a transient proceeding to higher outputs with a modular time constant $\tau_y\approx 5/2f$ seconds, as an example. The small negative value of $I_{L(n)}$ during the first half-cycle is due to the first two right-hand terms of equation 10. These terms arise from the transient voltage induced during the first half-cycle in the N_f turns associated with the shunt r_{s1}, and to the galvanic coupling of the shunt r_{s2}. Similarly, the negative value of $I_{f(1)}$ is due to the initial predominance of the transient voltage induced in the N_f winding. These effects are not very significant in any practical design. This point is mentioned to show that changes of output, in principle, appear this early during the first half-cycle as due to the magnetic and galvanic couplings.

The values acquired by the control current during the transient are of more serious concern. Considering the exponential rise of $y(t)$, equation 9 indicates that the highest value of $I_{c(n)}$ occurs for $n=1$ and is given by

$$I_{c(1)}=\frac{1}{K_\varphi N_c}\left(1+\frac{N_f^2}{N_c^2}\frac{R_c}{R_f}K_{EN}^*\right)\times \varphi_{p\infty}(1-\epsilon^{-\pi/\omega\tau_y}) \quad (12)$$

Hence, for a given design and thus for a given τ_y, the current $I_{c(1)}$ is proportional to the final steady-state value $\varphi_{p\infty}$, and hereby to the final gross output voltage, $E_\infty=2fN_g\varphi_{p\infty}$.

With a pure d-c signal, the energy demanded from the source in the first half-cycle is

$$U_1=E_c\int_{t=0}^{t=\pi/\omega}i_cdt=\frac{\pi}{\omega}E_cI_{c1} \quad \text{watt-seconds} \quad (13)$$

Since the signal applied is also proportional to the final output, it appears that, for a given design, the energy U_1 (or also the half-cycle average power $\omega/\pi\ U_1=E_cI_{c1}$) is proportional to the square of the swing of output prescribed.

It is interesting also to examine how the transient control currents and powers, and energies associated with a given swing of output, are affected if the time constant τ_y of the amplifier is modified by changes of the amount of negative electric feedback. The influence of τ_y on the control current of the first half-cycle $I_{c(1)}$ is shown in equation 12. For a given $\varphi_{p\infty}$, $I_{c(1)}$ varies proportionally to the factor

$$(1-\epsilon^{-\pi/\omega\tau_y})=\left\{\frac{\pi}{\omega}\frac{1}{\tau_y}-\frac{1}{2!}\left(\frac{\pi}{\omega}\frac{1}{\tau_y}\right)^2+\frac{1}{3!}\left(\frac{\pi}{\omega}\frac{1}{\tau_y}\right)^3-\dots\right\}$$

(and therefore is almost proportional to $1/\tau_y$ for time constants of two half-cycles or more). The dependency of E_c on τ_y is given by:

$$E_c=\frac{1}{K_\varphi N_c}R_c[1+v+K_{EN}^*(1+q)]\times \varphi_{p\infty}(1-\epsilon^{-\pi/\omega\tau_y}) \quad (14)$$

where

$$q=\frac{N_f^2}{N_c^2}\frac{R_c}{R_f}(1+v)$$

and

$$v=\frac{r_{s2}}{R_c}\left(1-\frac{r_{s2}}{R_g}\right)$$

The same factor $(1-\epsilon^{-\pi/(\omega\tau_y)})$ which appears in equation 12 appears here also. However, v is also a variable if changes of τ_y are achieved by changes of negative feedback resulting from changes of the shunt resistance r_{s2}. Decreases in τ_y obtained by increasing r_{s2} cause v to increase (if $r_{s2}<R_g/2$) and therefore E_c increases at a somewhat faster rate than $(1-\epsilon^{-\pi/(\omega\tau_y)})$. Altogether, one can say that the energy of the first half-cycle $U_1=E_cI_{c1}\pi/\omega$, for a given swing of outputs, is approximately proportional to $(1/\tau_y)^2$.

The total electric charge Q drawn from the source during the transient is given by

$$Q=\int_0^\infty i_cdt=\int_0^{\pi/\omega}i_cdt+\int_{\pi/\omega}^{2\pi/\omega}i_cdt\dots+\int_{(n-1)\pi/\omega}^{n\pi/\omega}i_cdt+\dots$$

$$=\sum_{n=1}^{\infty}I_{c(n)}\frac{\pi}{\omega}=\frac{\pi}{\omega}\frac{1}{K_\varphi N_c}\times\left(1+\frac{N_f^2}{N_c^2}\frac{R_c}{R_f}K_{EN}^*\right)\varphi_{p\infty} \quad (15)$$

It is interesting to note that the total charge Q does not vary if τ_y is varied. Hence, the total energy demanded from the source $U_{\text{total}}=E_cQ$ is dependent on τ_y in the same manner as E_c, i.e., U_{total} is approximately proportional to $1/\tau_y$. The results given in the foregoing do not support the suggestion that the response must be rapid in order to minimize transient power drain from the input.[5]

Fast response is readily obtained in the practical design of this self-balancing amplifier. The expression of τ_y indicates that the time constant can be made very short if one is prepared to accept low values of the voltage gain per turn, $K_{EN}=K_EN_c/N_g$. In this respect this amplifier is not different from any one of the amplifiers examined in reference 1. In this self-balancing amplifier, however, a reduction of the voltage gain K_E by an increase in the negative series electric feedback, does not appreciably modify the control-current requirements. In addition, the latter requirements are extremely small to start with because of the positive magnetic feedback. There-

B—Down, $R_c = 150$ ohms
C—Up, $R_c = 5{,}000$ ohms
D—Down, $R_c = 5{,}000$ ohms

fore, fast response can be obtained with lower steady-state control power requirements than in other amplifiers.

It may be interesting in particular to consider the speed of response that results for $K_{BN} = 1$. (This condition means $1/\beta_e \; N_c/N_g = 1$, i.e., $r_{s2}/R_g = N_c/N_g$.) In this case the approximate time constant τ_a, neglecting the delaying action of the coupled feedback loop, becomes simply $\tau_a = 1/2f$ seconds. This would imply that the output $E_{(2)}$ of the second half-cycle is only 63.2% of the final steady state. This inference is hardly justifiable since the approximate expression is now strained beyond its rightful limits and the modular expression must be preferred.

Consideration of the modular time constant τ_y, shows that a faster response is obtainable than the approximate expression suggests. For example, for an amplifier with Hypernik V cores $1^1/_2$ by 2 by 1/2 inches, 2-mil tape at 60-cycle and normal voltage, with $K_\varphi \approx 0.15 \times 10^{-3}$ ohms-second, with $N_f = 200$ turns so as to make $\beta_m K_B{}^* = 1$, and with $N_g = 3{,}000$ turns, $N_c = 400$ turns, and $R_g = 1{,}500$ ohms, the condition $r_{s2}/R_g = N_c/N_g$ yields $r_{s2} = 200$ ohms. With $R_c = 150$ ohms, this yields $\tau_y = 0.43$ half-cycle. This means that the preset flux level, $\varphi_{p(1)}$, established at the end of the first half-cycle is about 90% of the final steady state and accordingly the output of the second half-cycle is also about 90% of final. These calculations are in good agreement with the experimental results shown in Figs. 2(A) and 2(B). Fig. 2(A) shows the traces of output currents for a transient starting from an initial output of about 20% of maximum to a final output of 80% of maximum, while Fig. 2(B) applies for the reverse transient between the same limits. The trace of the output current of the second half-cycle indicates $I_{L(2)} \approx 90\%$ of final steady state, while the traces of subsequent half-cycles are no longer distinguishable from the final.

Even faster responses are possible by proper designs and the limiting case of the simple half-cycle delay is obtainable, as has been demonstrated to the authors by Dr. Geyger in his laboratory. However, under the criterion $r_{s2}/R_g = N_c/N_g$, the transient is still an exponential one, even though τ_y may be quite short. In fact, the oscillograms of Figs. 2(C) and 2(D) show that the criterion is not necessarily sufficient to insure a fast response. These oscillograms have been obtained for the same steps of signal voltage as in the cases of Figs. 2(A) and 2(B) respectively, after R_c was increased from 150 to 5,000 ohms. (Self-balancing operation was achieved in this case with only a minor readjustment of the bias current, but with no other changes in the system, and in particular, without changing the condition, $r_{s2}/R_g = N_c/N_g$.) A calculation of the modular time constant τ_y, yields $\tau_y \approx 3$ half-cycles and this agrees rather well with the gradual readjustments of output, half-cycle by half-cycle, that are displayed in the oscillograms. Thus the point is made that values of R_c, which are not too large in terms of steady-state performance, can increase the time constant quite noticeably. The half-cyclic average control current during the first half-cycle of the transient was evaluated as $I_{c(1)} \approx 3$ ma (milliamperes) for the case of Figs. 2(A) and 2(B) while the band of deviation of I_c in steady state was ±50 μa (microampere). For the case of Figs. 2(C) and 2(D), the value of $I_{c(1)}$ was evaluated at about 0.5 ma while the band of deviation of I_c was ± 25 μa in steady state over the range. The transient currents have much larger values than the steady-state bands and this justifies the simplifying assumption of perfect steady-state self-balancing used in this transient analysis.

CURRENT-BALANCE CIRCUIT

The difference equations describing the general system with K_φ constant over the range of outputs, and with a current source bias, are:

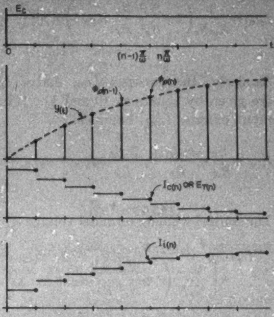

Fig. 3. Transient of preset flux φ_p, control winding current I_c, winding terminal voltage E_T, and input current I_i for a self-balancing amplifier of the current-balance type

$$I_{i(n)} = I_{a(n)} + I_{c(n)} \tag{16}$$

$$E_{c(n)} = R_K I_{i(n)} + 2r_c I_{c(n)} + 2fN_c(\varphi_{p(n)} - \varphi_{p(n-1)}) \tag{17}$$

$$E_{c(n)} = R_K I_{i(n)} + (R_a + r_{s2}) I_{a(n)} - r_{s2} I_{L(n)} \tag{18}$$

$$E_{g(n)} = 2fN_g(\varphi_s - \varphi_{p(n-1)} + R_g I_{L(n)} - r_{s2}(I_{a(n)}) - r_{s1} I_{f(n)} \tag{19}$$

$$r_{s1} I_{L(n)} = (R_f + r_{s1}) I_{f(n)} + 2fN_f(\varphi_{p(n)} - \varphi_{p(n-1)}) \tag{20}$$

$$N_c I_{c(n)} + N_f I_{f(n)} + \text{bias} = \frac{\varphi_{p(n)} - \varphi_K}{K_\varphi} \tag{21}$$

For a constant gate voltage E_g, considering only increments from some initial steady state, and assuming that the control voltage E_c is applied at the beginning of a half-cycle and remains constant thereafter, equation 6 is obtained again,

$$\zeta E_c = \varphi_{p(n)} - \alpha \varphi_{p(n-1)} \tag{6}$$

where

$$\zeta = \frac{(K_\varphi N_c/R_c)\dfrac{R_a + r_{s2}}{R_a + r_{s2} + R_K}}{1 - v + K_{BN}{}^*(1+q)}$$

and q, v, and α are given in Appendix II, under the approximations stated. For $0 \leqslant \alpha < 1$, the solution is again equation 8 where $\tau_y = 1/2f \; 1/ln(1/\alpha)$. Appendix II also presents an expression for τ_a, the time constant of the slow-transient approach.

In perfect self-balancing, the control winding current $I_{c(n)}$ obtained by solving equations 16–21 simultaneously with the condition $(1 - \beta_m K_B{}^*) = 0$, has again the form of equation 9:

$$I_{c(n)}=\frac{1}{K_\varphi N_c}\left(1+\frac{N_f^2}{N_c^2}\frac{R_c}{R_f}K_{EN}^*\right)\times (\varphi_{p(n)}-\varphi_{p(n-1)}) \quad (9)$$

Similarly, the currents $I_{f(n)}$ and $I_{L(n)}$ are given by equations 10 and 11. The input current $I_{i(n)}$, becomes:

$$I_{i(n)}=\frac{E_c}{R_K}-\frac{2r_cI_{c(n)}}{R_K}-\frac{2fN_c}{R_K}(\varphi_{p(n)}-\varphi_{p(n-1)}) \quad (22)$$

The control winding terminal voltage is

$$E_{T(n)}=2r_cI_{c(n)}+2fN_c(\varphi_{p(n)}-\varphi_{p(n-1)}) = \left[\frac{2r_c}{K_\varphi N_c}\left(1+\frac{N_f^2}{N_c^2}\frac{R_c}{R_f}K_{EN}^*\right)+ 2fN_c\right][\varphi_{p(n)}-\varphi_{p(n-1)}] \quad (23)$$

Fig. 3 shows plots of φ_p, I_c, I_i, and E_T for a transient proceeding to higher outputs with a time constant $\tau_y=5/2f$ seconds. $I_{c(n)}$ and $E_{T(n)}$ acquire their highest values in the first half-cycle ($n=1$), and their values $I_{c(1)}$ and $E_{T(1)}$ are obtained by substituting $\varphi_{p\infty}(1-\epsilon^{-\pi/\omega\tau_y})$ for $(\varphi_{p(n)}-\varphi_{p(n-1)})$ in equations 9 and 23. Both quantities are proportional to $\varphi_{p\infty}$, i.e., to the final steady-state output, and to the factor $(1-\epsilon^{-\pi/\omega\tau_y})$ which, for τ_y greater than two half-cycles, can be approximated by $\pi/(\omega\tau_y)$. This shows that smaller time constants, obtained by increasing the negative shunt electric feedback, imply higher initial disturbances of I_c and E_T in the transient.

Fast response again can be obtained if the voltage gain per turn is low[6] (under restrictions which are seen by examining the expression of α given). In this circuit, however, in contrast to the "voltage-balance" circuit, a reduction of K_E by increases of r_{s2} and/or by decreases of R_g, implies a reduction of the current gain K_A at about the same rate.

Conclusions

A previous analysis of magnetic amplifiers modified by feedbacks has been extended to two combinations of magnetic and electric feedback with particular reference to self-balancing operation.

For a "voltage-balance" circuit, expressions have been given for the steady-state gains, input and output resistance, and the influence of the control-circuit resistance R_c upon linearity and stability has been mentioned. During transients, self-balancing operation is upset. For a transient, caused by the application of a step of control voltage at the beginning of a half-cycle, it has been shown that the half-cyclic average control current of the first half-cycle as well as the total energy demanded from the source vary approximately as the reciprocal of τ_y, while the half-cyclic average power of the first half-cycle varies approximately as $(1/\tau_y)^2$. The matter of fast transients has been examined with the conclusion that an amount of negative electric feedback which causes the voltage gain per turn to be unity, can result practically in a modular time constant of fractions of a half-cycle and thus in an output response which approximates the simple half-cyclic delay. This is true for low values of R_c; the same voltage gain per turn gives slower transients if R_c is increased.

A similar analysis has been given for a "current-balance" circuit pointing out essential differences that result, in this case, because of the manner in which the negative electric feedback is applied.

A Nonsynchronous System for Mobile Record Communications

C. H. STEWART II
MEMBER AIEE

ONE OF THE MOST significant advances in the record communications industry occurred during World War II. This was not so much a technological advance, although this certainly occurred, but a change in operational requirements. The sheer bulk of communications which is required to control adequately and to support a highly mobile combat force plus the difficult communications problems which are posed by such mobile operations early dictated the requirement for more efficient and reliable communications than could be provided by conventional voice circuits. Voice communications are beset by the disadvantages of a relatively low transmission rate and an inherently high transcription error, plus the requirement for a relatively good communications circuit. Consequently, the volume of traffic which is assigned to ripnted record communications has steadily increased until currently the use of voice communications is largely limited to short-range command functions; it is conceivable that, in the not too distant future, even this function will be supplanted by highly portable printing telegraph systems.

The growth of civil printed record communications has developed by an analogous process, although this growth has not been quite as spectacular. The increasing acceptance of data-processing and control systems requires an increasing use of printed communications techniques, to such an extent that the mass of high-speed printed communications which present-day users believe to be absolutely necessary would once have been thought of as a luxury. Many manufacturing processes involve significant field operations which include a sizable mobile force, so that two-way transfer of data is becoming increasingly important to this class of user. The current philosophy of many companies is that this two-way transfer of data naturally extends to the field operations, and it would appear that an ever increasing number of organizations are coming to this point of view. The commercial air carriers are a particularly good example of this philosophy. Presently, their communications requirements are being filled by relatively inefficient voice circuits; however, recent aircraft developments, notably the advent of jet aircraft, have convinced operations personnel that a more efficient means of transferring data is an absolute requirement. This will apparently be handled as a two-stage process, initially by means of a conventional printed

Paper 59-8, recommended by the AIEE Telegraph Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted June 26, 1958; made available for printing October 16, 1958.

C. H. Stewart II is with the Bell & Gossett Company, Morton Grove, Ill.

In addition to many people within the Bell & Gossett Company who made significant contributions to the system development, special recognition should be accorded to J. D. Durkee for the basic system concept and for his many continuing contributions. Special credit is also due the consulting firm of Jansky & Bailey, Inc., of Washington, D. C., for their invaluable assistance in the basic explorations and engineering model development.

record communications operation which can later be expanded to a high-speed system for automatic data processing.

The effectiveness of synchronous systems for handling data at high transmission rates with reasonable circuit efficiencies has been demonstrated over a long period. Previously, attempts to extend this technique to services other than land line or fixed plant point-to-point communications circuits have experienced severe difficulties. One of the principal long-term difficulties has been the maintenance of synchronism over the relatively poor communications circuits which generally exist for mobile services. In recent years, several promising approaches have been made toward solving this synchronism problem. One partial solution has been provided through the use of electronic commutation to obviate the requirement of providing a closely controlled rotational rate for the printing telegraph motor. Other approaches add to this the use of a highly redundant binary code and more sophisticated synchronizing means. A radically different approach is that which depends upon a completely nonsynchronous transmission system. Such a system has been developed by the Bell & Gossett Company in co-operation with the Dualex Corporation; and is currently produced under the trade name of the Unitone System. It is this system which will be discussed.

The basic design objective was the provision of a highly reliable mobile extension to a land line or point-to-point record communications–data-handling system. To be completely useful, such a system must provide reliable communications for a circuit which would be marginal or completely unusable for other communications services. As a secondary requirement, it should be possible to implement the system without extensively modifying the existing communications circuit, since a large portion of the potential users currently have some type of communications system. A brief summary of the desired system characteristics follows:

1. Since the system would be essentially an extension to a printing telegraph network, the basic coding scheme should be compatible with the conventional 5-bit printing telegraph code.

2. Circuit reliability requires that the system should employ a slowed-down bit rate for a given transmission rate. This provides an increased sampling period for each bit with a corresponding increase in reliability. This sampling should be provided in a nonsynchronous manner so that the most effective use could be made of the circuit quality which exists at any time.

3. The existing mobile communications circuits are predominately voice circuits; therefore, some type of tone-coded signals would appear to require no equipment modification.

4. Since the system is primarily for mobile applications, a duplex terminal should be provided with low volume, weight, and power consumption.

5. The initial system transmission capacity should represent a reasonable compromise between the requirement for a high-speed data-handling system and the transmission rate which would be required for printed record communications purposes per se. A maximum system capability somewhat in excess of 100 words per minute appeared to be a reasonable compromise, since it would not require a prohibitive development period.

7. The system should be designed with a minimum of complexity, consistent with the desired performance, in order to minimize maintenance problems.

Design Approach

One of the first parameters requiring development was that of the specific coding scheme to be employed. The system requirements were based on a 5-bit code, and the coding system obviously had to be tailored to this requirement if some auxiliary code conversion process were to be obviated. The requirement of a type of tone-coding applied to the 5-bit code would indicate, as an initial approach, the simultaneous transmission of combinations of five audio-frequency tones representing the marking condition of each of the five code elements which comprise the printing telegraph code. Although, at first blush, this would appear to provide "the solution," it is apparent that the advantage of an increased sampling period which thus accrues is essentially nullified by the effective "per-frequency" power reduction resulting from simultaneous transmission. It was also apparent early in the development program that it would be impractical to attempt to utilize the entire character period for sampling since this would require a complex intermediate buffer storage. Thus, if the ultimate performance were to be provided with a minimum of circuit complexity, a different technique would be required. However, it should be noted that a number of prototype units of this so-called Pentone system were constructed which proved very successful for circuits which would normally be considered as marginal for voice communications service.

An evaluation of the relative importance of sampling period versus per-frequency power indicated that the optimum coding system should use alternate transmission of two equal length audio-frequency tones. This would provide maximum effective signal power per tone and also a sampling period approximately four times as long as that of a 5-bit start-stop asynchronous system operating at the same over-all transmission rate.

Fig. 1 illustrates the coding and sampling relations between these two types of systems. The first and second phase tones indicated in Fig. 1 are the bit frequencies from the two families (four and eight respectively) which are transmitted in a consistent time relation, i.e., one of the frequencies of a first family of four always precedes one of a second family of eight. The correspondence between this coding and the 5-bit printing telegraph code occurs in the use of a given frequency to indicate the code element combinations. For example, the four first-phase frequencies represent the combinations of code elements 1 and 2 (1-0, 0-2, 1-2, and 0-0). The second-phase family similarly corresponds to the combinations or code elements 3, 4, and 5. Thus it may be seen that only two bits are used to convey the information contained in the 5-bit code resulting in a significant reduction in effective bit rate. At the receiving terminal, in the stand-by condition, the entire first-phase family of frequencies is exposed to the communications circuit. Statistically, the most reliable operation would appear to be provided by the use of a single first-phase conditioning frequency, at the expense, however, of requiring a second-phase family comprised of 32 frequencies. The increase in reliability was not believed to

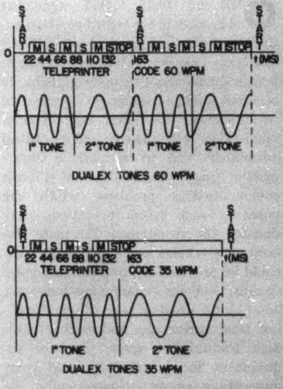

Fig. 1. Comparison of Dualex tone signal with 5-bit start-stop d-c signal

be sufficient to justify this large family of frequencies. The optimum compromise between reliability and frequency complement was found to be the use of a first phase family of four frequencies and a second-phase family of eight frequencies.

To derive the maximum performance which can be provided by the nonsynchronous nature of the system, the receiving terminal should employ a variable bandwidth technique, for, as the circuit deteriorates, it should be possible to reduce the transmission rate and correspondingly automatically reduce the bandwidth of the frequency detectors at the receiving terminal, thus allowing full advantage to be taken of the longer sampling period. This operational characteristic can be closely approximated through the use of conventional filters and rather complex circuitry. The complete realization of this approach requires that very tight tolerances be maintained on the filter characteristics and various threshold levels. This is difficult to achieve in practice. In view of the complexity of this approach, it appeared to be incompatible with the design criteria. A study of the potentialities of resonant reed relays showed that they inherently possess many of the characteristics which are required in the provision of a variable bandwidth system of minimum circuit complexity. This comes about largely from the fact that the output of these relays is a sequence of low-impedance contacts which occur at well defined threshold levels. The absolute value of this threshold is directly dependent upon the method of applying the driving signal. Also, in direct analogy to conventional filters, the response time is inversely proportional to the bandwidth. Thus, it is readily appreciated that the principal ingredients for a variable bandwidth system are inherent to the intrinsic device parameters. One of the characteristics which make the reed attractive, namely, the very high effective Q, makes it impossible to realize keying rates in excess of a few words per minute. The bandwidth–build-up characteristics can readily provide acceptable bandwidths for rise times which are adequate for transmission rates well in excess of 100 words per minute, but the mechanical Q of the reeds is sufficiently high that the reed may never be completely at rest at keying rates over 50 words per minute. The net result is a very erratic build-up time. Extensive testing of the commercially available resonant reed relays showed that none of the units could be successfully utilized for the proposed application.

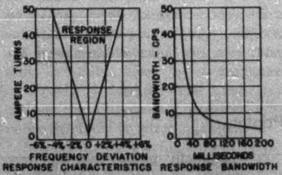

Fig. 2. Resonant reed relay characteristics

The many attractive characteristics of this type of unit appeared to be sufficiently valuable to warrant a development program. It will not be possible in the allotted space to discuss this developmental program; suffice it to say that a practical unit has evolved. Fig. 2 indicates a typical response curve and bandwidth–build-up time relation for the relays as they are currently produced. The solution to the reduction of the reed decay time is currently provided by an electromechanical friction-quenching system. The use of an inertialess measuring technique shows typical damping periods of 10 milliseconds or less. Although this damping factor is more than adequate for sampling rates in excess of 100 words per minute, investigations are continuing toward developing better damping methods.

An examination of the possible methods for driving these units revealed that a constant-current technique would be required in order to achieve the requisite stability and performance. This is because the over-all driven circuit (reed and drive coil) is the responsive in a dual resonant mode about the physical resonance of the reed, so that the impedance of the reed drive coil undergoes a significant fluctuation as the generator frequency is varied through the resonant frequency of the reed. The over-all reed performance is improved, for certain conditions, when the coil circuit is electrically resonated. Because of the intimate relationship between the physical resonance of the reed and that of the reed drive coil, caution must be exercised in establishing the tuning criteria. It is interesting to note that the over-all tuning procedure, which has been utilized for the reed relays for this service, constrains the response characteristic to one which is essentially symmetrical about the resonant frequency rather than the geometric response which would be anticipated for this type of resonant circuit.

Determination of the range of transmission rates to be accommodated by the system immediately fixed the limits for the reed threshold level and, correspondingly, the effective individual bandwidth. The design criteria for accommodation of transmission rates, from approximately 5 to 100 words per minute, indicated that reed threshold response periods ranging from approximately 700 to 25 milliseconds would be required. The resulting maximum bandwidth of approximately 25 cycles allowed for a minimum frequency separation of 40 to 50 cycles, provided that a definite upper limit was placed upon the amplitude of the drive level. The adjustment procedure utilized for the relays results in a threshold-bandwidth-drive level relationship which is essentially independent of the center frequency. As a result of the essentially constant bandwidth, a constant frequency separation of approximately 43 cycles was chosen in lieu of the usual logarithmic separation. The adjustment procedure which yields this constant bandwidth characteristic does result in a variation in absolute sensitivity, i.e., the nose of the response characteristic, which is inversely proportional to the center frequency. This variation in absolute sensitivity becomes the factor which limits the operation under extremely degraded circuit conditions so that it is not feasible to decrease the transmission rate below approximately five words per minute.

The remainder of the development effort was concentrated on the terminal equipment circuitry and printing system. Since the two programs required radically different approaches, they will be discussed separately.

Terminal Unit

Fig. 3 is a simplified block diagram of a typical duplex terminal. Entry to the transmitting converter is on a parallel basis, and is normally accomplished by contact closure of the five code switches on the keyboard or tapereader. The sixth switch performs a dual function of actuating the timing relay and providing simultaneous output of the five code element switches without requiring individually precise adjustments. The five code switches drive five relays whose contacts are arranged in a double "pine tree" matrix deriving the 32-function code.

These contacts select the output of a pair of oscillators whose frequencies correspond to the function which has been selected by the keyboard or tapereader contact combination. The timing relay sequentially switches the amplifier input between the output of the first-phase and the second-phase matrices so that the unique time sequence is maintained. When the input is generated by a tapereader or, if manually generated by a

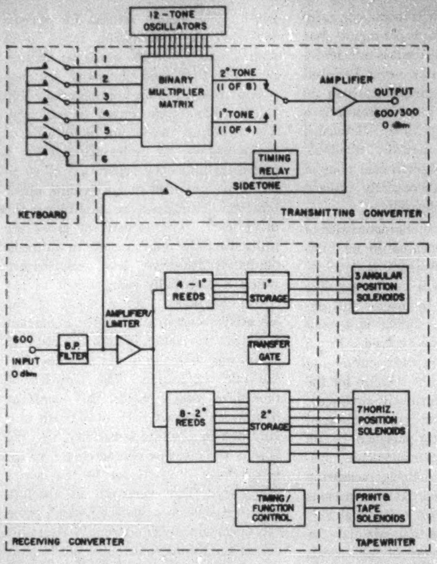

Fig. 3. Simplified block diagram of duplex terminal

trained operator, the time division between the first- and second-phase frequencies is sufficiently accurate that auxiliary timing circuits are not required. When it is anticipated that relatively inexperienced operators will operate the circuit, an auxiliary plug-in timing relay is utilized. This relay limits the length of the first-phase tone and thus minimizes the effect of operator timing error. The amplifier output is squelched during the stand-by period so there is no possibility that tone leak-through will interfere with circuits which are used for voice communications on a shared time basis. A normally open contact is also provided for use with those equipments having a "push-to-talk" mode of operation. This circuit has a release delay of approximately 750 milliseconds, providing for no carrier interruptions for keying rates in excess of approximately five words per minute. Inasmuch as the normal installation would be on existing voice circuits, the nominal output was chosen as zero decibels referred to one milliwatt. Provision is made for monitoring the transmitted copy by means of a side-tone amplifier whose output is well in excess of the input threshold of the receiving converter.

The receiving converter consists of three basic subdivisions: the preliminary filtering and amplification (which provides the drive for the reed detectors); the frequency determining elements (reed detectors); and the storage and timing circuits. It will be noted in Fig. 3 that a limiter-amplifier combination is used to provide the drive to the resonant reed relays. The reason for this is twofold: first, to preclude the possibility of printing erroneous characters, driving power must be limited in order to prevent the reed threshold from being raised to the point where a given reed responds to adjacent frequencies; second, the quasi-capture effect of a broad-band limiter increases the effective signal-to-noise ratio if it is greater than unity and depresses the reed signal power for signal-to-noise ratios less than unity. This limiter effect tends to reduce the drive to the reed detectors and correspondingly the acceptance band for signal-to-noise ratios less than unity so that the effective bandwidth is essentially proportional to the signal-to-noise ratio. Thus, the desired variable bandwidth system performance has been approximated by means of relatively simple circuitry.

The transfer gate initially conditions the first-phase family of reed detectors so that all four are exposed to the communications circuit. Upon recognition of one of the first-phase frequencies, the appropriate code is stored and, simultaneously, the gate conditions the second-phase family of frequencies. Upon recognition of a second-phase frequency, this information is stored and simultaneously the print cycle is initiated. With the present printer, the print cycle consists of approximately 50 milliseconds' positioning time, plus 25 to 30 milliseconds' printing time. The time which is required for the overall sequence of relay operations, plus the print cycle time, requires that it be possible to store succeeding first-phase information during the print cycle in order to achieve transmission rates in excess of approximately 85 words per minute. This is accomplished by utilizing a compound first-phase storage, i.e., buffer storage plus output storage.

It will be noted that a 12-wire output is required by the printer (10-code element plus print and return leads). To accommodate the use of tape perforators or other auxiliary equipment, the output storage incorporates a binary divider so as to provide a 5-wire parallel output. It should also be pointed out that since the storage is accomplished by means of relays, the circuit is arranged so that only two heavy-duty relays make or break the output current, thus reducing contact wear.

As a consequence of the high use factor for the radio-frequency spectrum, the incidence of co-channel and adjacent channel interference is quite high. To provide protection against interfering components' falling within the signal band, an additional timing circuit was incorporated in the transfer gate. The function of this circuit is to clear the first-phase storage if a second-phase frequency is not recognized within a certain period of time. This time is determined by the length of the first-phase frequency; thus, the period which is allowed before clearing is determined by the effective transmission rate. This circuit has greatly reduced the sensitivity of the system to interfering signals although it is manifestly impossible to preclude such errors completely by this approach.

Early in the design program, it was quite evident that a stabilized low-impedance voltage source would be required for the gating and timing functions. This is provided by a regulated supply whose output impedance is less than 5 ohms for a frequency range of direct current to 200,000 cycles, so that no instability results from any pulses which may be encountered.

Printer

It was initially decided that the overall system requirements dictated a fresh approach to the printer problem, rather

Vol.
Pt. 1
195

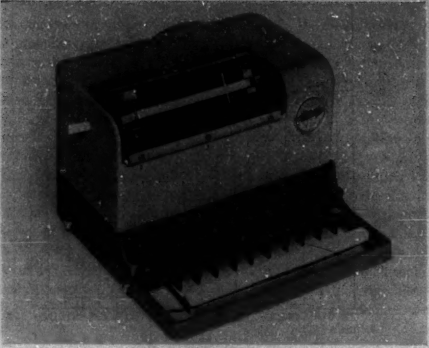

Fig. 4. Tapewriter and keyboard

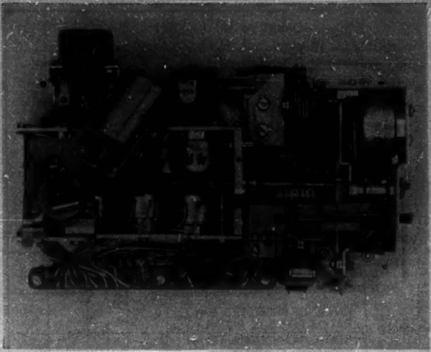

Fig. 5. View of tapewriter with cover removed

than the attempt to modify an existing unit. After thorough exploration of the many possible approaches, it was decided that the requirement for satisfactory operation under difficult environmental conditions, plus the requirement for minimum size, weight, and power consumption could best be met by a tape printer configuration. The basic mechanism consists of rotary solenoids driving a type segment arranged in a 4-by-8 matrix. This approach results in minimum power consumption since no power is required except during the printing operation. Fig. 4 shows the assembled printer and keyboard. The type segment arrangement as a 4-by-8 matrix requires seven active horizontal positions and three active angular positions. The seven rotary solenoids and associated linkage constitute the subassembly in the left foreground of Fig. 5. The angular positioning subassembly, which consists of the three solenoids and associated linkage, comprises the assembly at the extreme right. It will be noted that the type font is reversed so that the tape is between the operator and the type font. This configuration provides maximum visibility. To reduce further the mechanical movements to a minimum, the conventional paper tape plus inked ribbon combination has been discarded in favor of impact-sensitive tape. Upper and lower case selection (figures-letters shift), is accomplished by rotating the tape guide 11 degrees. This subdivides each of the 32 type font positions into either the figure or letter characters.

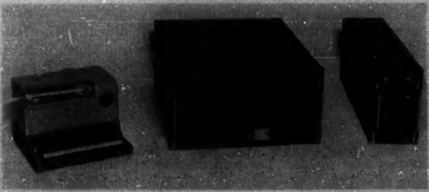
At present, the driving current is applied as a discontinuous pulse; however, a subsequent model of the system will provide tailored driving pulses so that all of the movements will be subjected to simple harmonic acceleration.

Results and Conclusions

Fig. 6 shows a typical duplex terminal developed by the program. The converter and power supply are packaged in the standard ATR (American Television & Radio Company) configuration since it was anticipated that the initial use would be in an air-borne environment due to the stringent communication requirements of this service. The major objective of the design program was the development of a system which approached the performance capability of the basic concept, making it possible to acquire a useful quantity of data from actual field service. A miniaturization program is being initiated which should result in significant improvements in the over-all performance and major reductions in the displacement, weight, and power consumption. The maintenance-free life should also be greatly extended since solid-state switching is planned for all of the circuits.

The over-all system performance has been extensively measured in the laboratory. The results of a typical test are shown as Fig. 7. This test utilized a white noise source, band limited to the signal band by an inductance-capacitance filter with 40 decibels per octave skirt selectivity. The rms noise envelope is plotted versus the maximum transmission rate for an error count equal to or less than 1%. It will be noted that the curve directly shows the quasi-capture effect of the limiter on the reed detector bandwidth and corresponding threshold build-up time. It will also be noted that, because of the maximum speed capability of the system, the deviation from the logarithmic relation between the signal-to-noise ratio and channel capacity increases at the higher transmission rates. The zone which is shown as 50% error for 5-bit synchronous systems is the predicted signal-to-noise ratio for this maximum error rate as described by Masonson[1] and Montgomery.[2] The indicated range includes both amplitude modulation and frequency shift keying for noise, band-limited to the transmission band. Although the predicted performance of the binary systems is based on several simplifying assumptions, the improvement in performance provided by the nonsynchronous approach is believed to be significant.

Fig. 6. Type U2-A typical duplex airborne terminal developed by the program



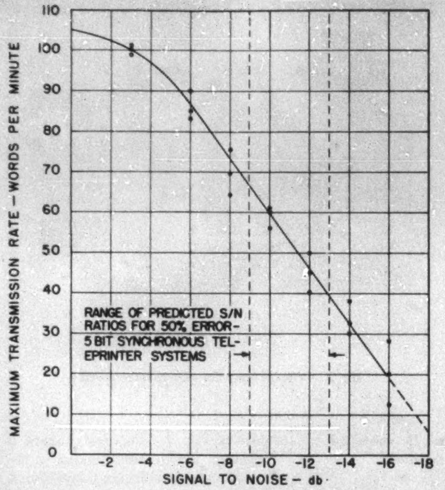


Fig. 7 (left). Maximum transmission rate for 1% error

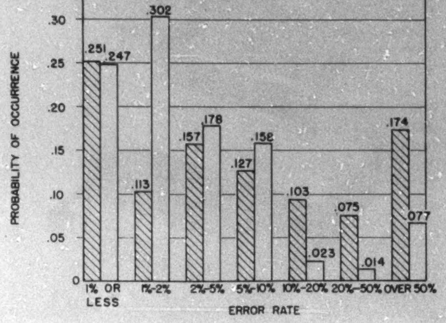

Fig. 8 (above). Wright Air Development Center flight tests, 1956. Shaded areas—frequency shift keying. Unshaded areas—Unitone DSB-AM

The "proof of the pudding" for any system, of course, is the performance under actual circuit conditions. The system has been flight tested by the Department of Defense with various test objectives. Two of the more quantitative test programs will be briefly described.

One of the earlier tests was conducted by the Air Weather Service in February 1956.[3] The purpose of the test was to compare the system performance with that of voice and manual CW (continuous wave) techniques. Inasmuch as it was desired that the program also furnish operational suitability information, the transmissions consisted of the operational traffic which was generated by the weather reconnaissance flights from Kindley Air Force Base, Bermuda. The weather reconnaissance tracks flown were essentially a triangular path of approximately 1,100 miles per leg. Each message was transmitted in sequence as rapidly as possible by manual CW, voice, and the Unitone system in order to minimize variations in propagation conditions. Conventional double side-band amplitude modulation was utilized for the voice and Unitone transmissions with equal carrier power maintained for all modes of transmission. The effective power output from the air-borne transmitter was less than 100 watts and the ground transmitters were operated at a nominal power level of 3,000 watts. The transmissions were scored on a per-character basis by directly comparing the transmitted and received copy. The following conclusions were based on an analysis of the test results. The voice transmissions were sufficiently ineffective that no relative comparisons were attempted. The Unitone transmissions were found to be as effective as the manual CW, and for very degraded circuit conditions appeared to be somewhat superior, especially regarding effective transmission rate. This was indeed gratifying since manual CW has long been the standard of comparison for the performance of degraded circuits.

During June and July of 1956, the Communications and Navigations Laboratory at Wright Air Development Center conducted a more quantitative test, to compare the performance of the Unitone system with that of a frequency-shift keying teleprinter system.[4] Consequently, all transmissions which were utilized for scoring purposes used prepared test tapes and mechanical transmission for both systems. Transmissions, in each mode, were made sequentially in 3- to 5-minute increments in order to minimize variations in propagation conditions. The aircraft radio-frequency equipment was an *ARC-21* transceiver plus an *XA-4* exciter for the frequency shift keying transmissions. The test flights varied from 400 to a maximum of 1,700 miles. The operational frequencies for each period were selected at the three extremes of frequency usage. During each hour, one series of transmissions was made on the optimum traffic frequency, the second on a frequency which was above the predicted maximum usable frequency, and the final sequence utilized a frequency which was below the predicted lowest useful frequency for the particular path. The circuit was often further degraded by adjusting the azimuthal orientation of the ground antenna system away from the propagation path.

A total of 74,362 characters, for each mode of transmission, was retained for scoring purposes. The general conclusions resulting from the test programs were that, for good circuit conditions, the performance provided by both techniques was essentially equivalent; but that, for deteriorated circuit conditions, the Unitone system, in the aggregate, provided a better "per-character" reliability of 15% to 25%. Fig. 8 shows the results of the flight test program, presenting the data as probability of occurrence for various error rates for each mode of transmission. The error rates are grouped logarithmically since this provides the best indication of the over-all system usefulness. As would be expected for error rates of 1% or less, the two systems provide an equivalent probability which indicates simply that, for a reasonably good transmission medium, the choice of technique is not very important; however, for deteriorated conditions the differences are more pronounced. For example, the Unitone system, for the wide range of circuit conditions, exhibited the highest probability for error rates of 1% to 2% with the probability of higher error rates decreasing rapidly. The frequency shift keying system, on the other hand, exhibits a probability peak for a 2% to 5% error rate with a relatively gradual decrease in probability for higher error rates. It is also informative to compare the probability of occurrence for error rates in excess of 50%. Although it would certainly be a grave error to draw sweeping conclusions from the limited test data, it is believed that they are an indication of the potentiality of this technique. It is believed that the differences would have been even greater had the modulation system been other than double side-band amplitude modulation. For example, a series of propagation-modulation tests which were conducted by the Bell & Gossett Company over a 600-mile path indicated that the use of a narrow-band frequency modulation technique such as proposed by Arguimbau resulted in an effective power gain of approximately 6 decibels over double side-band amplitude modulation.

The system described is currently being produced for use by the Air Defense Command as the primary air-ground communications system for the Airborne Early Warning environment. As a part of this program, a duplex serial to parallel adapter has been developed and is in production for installation in the ground environment. The adapter provides direct entry into a conventional start-stop 5-bit telegraph system. Decreased maintenance requirements are provided by the use of modular packaging techniques and solid-state circuitry throughout.

The laboratory testing and, to date, the somewhat limited flight testing of the Unitone nonsynchronous system indicates that this approach provides increased reliability for difficult communications circuits. The equipments which are currently under development should provide even better performance which more closely approaches the ultimate system capability.

Industry Schools Its Engineers

C. E. WALDNER
MEMBER AIEE

WHY IS INDUSTRY starting and expanding programs to educate its young engineers beyond the level where formal education left off? Why is it reviewing the education of its older engineers and giving them further training? Are not the great universities offering their students the proper curriculums?

The answer, of course, is that, while the universities are doing a fine job, technologies in almost every field are changing and advancing so rapidly that a formal education begins to be out of date in a period of only a few years. For instance, that which is no more than a theory during the college student's freshman year may become a practical project and go into production during his senior year, taking only 4 years to materialize. Consequently, industry, to keep pace with these advances and changes, and to ensure that there are those available who understand and can handle the new technologies, must take the initiative in training its people, particularly in areas requiring specialized education.

Training in Industry

In the telephone business, one is constantly impressed by the depth and scope of present-day formal education in communications. Many an "oldtimer," who himself may have been able to take only one or two elective hours of communications in his mechanical and electrical engineering college, is struck by the knowledge and the fluency of those who major today in communications, in discussing theories involving transistors, waveguides, radio, etc. Yet, in the telephone business particularly, the need for such educated personnel far exceeds the supply.

During the last two decades, industries that have entered the field of electronics have multiplied many times and their demand for these college graduates has become great. It is not the telephone systems alone that require their services: now, there are data-processing and transmission, guided missiles, special communications for jet planes, not to mention the much advertised trip to the moon.

There is also the need to consider for such training the present Bell System engineering manpower, a core of experienced and capable people who, during 1958, added plant that requires an expenditure of over 2 billion dollars. The experience of these men (and there are some women engineers) ranges from less than 1 to more than 40 years. Some are engineering graduates; others are without college degrees. Among the former, very few have majored in communications, and a relatively small number are conversant in the newest arts. (This does not apply to those whose hobbies are in connection with radio, nor to those who have gained knowledge through self-study and actual experience, nor to the highly knowledgeable experts of the Bell Laboratories.)

Yet it is among these existing engineers, where planning for the future more than ever before is rapidly leading into the new electronic arts, that the need for knowledge and information is most acutely felt. For example, formerly open-wire and cable afforded the only conversational channels; now carrier and radio are taking a larger and larger share. Any circuit that operated efficiently on voice frequency, say, between 200 and 3,000 cycles, used to meet requirements; now kilocycles and megacycles are involved, with

C. E. Waldner is with the New York Telephone Company, New York, N. Y.

Special credit is due to Cornell University for accepting and carrying out this program. Acknowledgment is also due to the following for their assistance in organizing the training course: Prof. W. H. Erickson, director, School of Electrical Engineering, and Dr. H. G. Smith, professor of communications, Cornell University; Dr. J. K. Lamond, C. N. Anderson, P. A. Jeanne, and L. C. Roberts, former Bell System engineers, now instructors at Cornell University; F. H. Tallman and M. B. Zaret, professors of communications, Cooper Union; W. R. Silvey, S. Hayward, and R. C. Crawshaw, engineers of outside plant and transmission, and H. M. Wilson, transmission engineer, New York Telephone Company.

transmission making essential circuit refinements that were previously unheard of. And, in a relatively few years, switching systems will no longer exclusively use magnetic relays but rather diodes, transistors, and cold cathode tubes. And there is more to come!

The practice of training engineers has been active among Bell System companies for some time. It has been applied to equipment engineers, who lay out, order, and oversee the installation of switching and auxiliary apparatus; the outside plant engineer, who is responsible for poles, cables, and subways, and to others of the engineering fraternity.

The advent of modern electronics, however, has revolutionized the field of telephony. This has brought the need for a whole new technical orientation which can be met only through a new, specialized educational program, the development of which has required the establishment of new evaluation and training methods and the setting up of additional educational facilities. In telephone parlance, the electronics engineering trainees are known as communications engineers in a field which telephone people, with justification, refer to as the New Arts.

The telephone industry, then, like many other industries, is increasingly taking on the aspect of an educational, as well as a service, institution. Telephony is progressing at its most rapid rate in history. Therefore it is essential that the industry foster the education of its engineers in the new arts of communication. It is only through continuous study of the latest sciences that the communications world of tomorrow can be designed, built, and perfected.

The New York Telephone Company Program

Since early in 1956 the New York Telephone Company has given in-hour, off-the-job training over periods of from 1 to 3 weeks to about 800 of the central office, outside plant, and customer equipment engineers. During the last year it has had 2,300 enrollments in a correspondence school. This type of training will be continued as new equipment is provided and practices change, and also as engineers are transferred or new ones are brought into the business. To meet the needs for engineering in electronics, however, it was felt necessary to obtain the facilities of a large university in the curriculum of which communications played a predominate part. After considerable investigation, a school for communications

engineers was eatablished at Cornell University, starting with the school year beginning in September 1957. Each student attends three 3-week sessions spaced about 4 to 6 months apart, with a maximum of 24 students in his class. The sessions have been planned to run continuously for 2 years, excluding summer months and several regular college recesses, and to terminate in June 1959. Altogether, 200 engineers are receiving training.

Many problems were encountered in organizing the training course. It was necessary to bring together into one class men from widely different eras in college education, with varying degrees and types of education and of company experience. Instructors with considerable knowledge of these subjects were required. These and other requirements had to be met before a successfully operated school could be realized.

It was recognized that for successful training, any great scholastic level discrepancies among the students would have to be avoided. For instance, if higher mathematics were the subject being taught, a man with little education would retard the progress of the entire class. Therefore, to measure qualifications for this communications training program, a 4-hour examination was developed and given to over 300 engineers, including also some Plant Department supervisory people. It consisted of two parts, mathematics and electronics, the former being a prerequisite, of course, in any studies of the latter. After a large sample of the answer papers had been reviewed in order to determine some representative and practical grouping, all papers were marked and the engineers segregated into three categories: 1. men not qualified to enter into the high standard of education contemplated until they had taken prerequisite courses in mathematics and in a-c circuits, 2. men qualified after taking the course in a-c circuits, and 3. men qualified without the advanced training recommended for categories 1 and 2.

Another very important function of this examination was to determine the curriculum, and the depth of training needed. There would have been little point for the average student in going into higher mathematics or the most recently advanced theories of electronics if he actually required training to bring him to a standard below this level. Also, the college graduates of years ago, without daily usage of their undergraduate learning, needed refresher courses. The company considered these factors when selecting the subject matter for instruction. Therefore, for the initial period, or phase A of training, a review of the general principles of transmission lines and basic electronics was concentrated upon. The plan was to cover this in 3 weeks with 60 hours of classroom work and 18 hours each of computation and laboratory periods; see Fig. 1.

Other subjects were contemplated at this time but it was decided not to set up a further definitive program until later. It was felt that it would be helpful, in laying out the studies subsequent to phase A, if first the students' reactions and their progress on the initial phase were observed, there followed up with a curriculum neither too far above nor below the capacity and level of the average. Therefore, after the completion of two sessions of phase A, and with the foregoing factors in mind, phases B and C were formulated, with timing similar to that of phase A, as previously described; see Figs. 2 and 3.

The duration of any training course is most difficult to determine. Economy and available manpower play a part as important as training depth and needs. Sacrifices, sometimes extreme, must be made, as when, during the training period, the older engineers are obliged to isolate themselves from their families. Therefore, compromise is in order. In the

case of the Bell System course, the weighing of the various factors (without benefit of an exact science) led to the plan of using three 3-week periods, or a total of 9 weeks. To absorb so much in so little time was not found easy by the students. Extensive homework was a necessity, and former college students recalled what it meant to "burn the midnight oil."

It may be well to relate the means taken to prepare certain of the prospective students for this curriculum. As mentioned earlier, preliminary examination of the students indicated that some of them required preliminary training to qualify for the course. Subjects planned for phase A and tentatively for phases B and C were reviewed and compared with the test results. There was sufficient indication of weakness in mathematics to warrant the development of two courses, Mathematics 11 and 12, the first a prerequisite for the second; see Figs. 4 and 5. Also, EE 13, an advanced course in a-c circuits was planned; see Fig. 6. These courses were designed for an instruction period of 3 hours, 1 day a week, for 7 to 8 weeks depending on the capabilities of each class. To reduce the time and the expense of traveling throughout the state, separate classes were organized as required, in the larger cities and towns, and instruction was given by a faculty member of the local college or university. With such competent instructors, the results were very favorable. In fact, experience has shown that many of the students who participated surpassed others in the Communications School who, based on the pre-examinations, were considered exempt from this preliminary training.

The selection of a faculty and a location for the new arts training did not prove to be very easy. Inquiry at several schools indicated an extreme shortage of instructors and, because of this, talent within the telephone industry was sought. It was immediately evident that active employees, competent in the skills and techniques of the new arts, were so engrossed in current problems that they also were unavailable. However, there is the never-ending flow of retiring engineers, particularly from the Bell Laboratories; experienced men with a wealth of knowledge, and the determination to remain active. This provided a source of supply from which teaching material could be readily drawn. Fortified with the required number of such talented men, the program was found to be acceptable by the School of Electrical Engineering at Cornell University. By accepting these men on its faculty and supplementing them with a few of its regular communications professors, the university has organized for the Bell System a well co-ordinated new arts course.

Living accommodations take on the collegiate atmosphere. The students taking the course live on the campus and, for sociability and group study, have been provided with space on the third and fourth floors of one of the smaller dormitories for their own use. Meals are served to the group as a whole in a private dining room, also located on the campus. Classes, and computation and laboratory periods, are held in Phillips Hall, the Electrical Engineering building. As previously mentioned, there are 24 students attending each session; actually, to obtain increased student participation and closer instructor-student relationship, a smaller number would have been preferred. However, the total number to be trained within the time limit required this larger group. To sample the progress of the students, a written examination was scheduled every Friday afternoon.

An important adjunct to the program was a special appreciation course for engineering management so that management, could become familiar with what their engineers were being taught. This course consisted of a 2-day combined lecture and laboratory session for the supervisors. It was designed not only to meet the requirement just mentioned but also to impart some general knowledge relating to the subjects taught. Such an Appreciation course should be mandatory in any training course plan.

The tasks of screening the engineers by pre-examination, providing advance training to those who needed it, and selecting the curriculum, the instructors, and the college were accomplished not necessarily in the order given nor independently. Rather, all were undertaken practically simultaneously, relating as they did to a closely integrated program. Many compromises were made, such as those in connection with the period of training and the size of classes. However, the company has the compensation of a well-coordinated educational program with sufficient emphasis on telephony so that the engineers, in living up to the tradition of this industry, may plan for better service at lower costs. The success of the program provides a striking example of cooperation between businessmen and educators for the common cause of technological improvement and advancement.

◆

Discussion

Ellis F. King (University of California, Los Angeles, Calif.): Mr. Waldner explains why industry must provide additional schooling for its engineers. Perhaps the term "education" is preferable as opposed to "training" for programs of this nature, but no fault is found with his conclusions.

Indeed, important additional evidence is found of fundamental changes in higher education patterns which reinforce his argument for increased industry-sponsored programs. Paradoxically, future engineering graduates will be both better educated and more in need of courses such as the ones described.

The trend in major engineering schools is toward more fundamental concepts at increasing levels of sophistication. The graduate of the future will be more broadly educated at the expense of knowledge of the techniques of a particular industry. And rightly so, for it is here that the colleges and universities can make their optimum contribution to the individual's eventual development to professional stature. For example, the advent of the transistor greatly reduced the value of a body of preceptual knowledge concerning vacuum-tube parameters and techniques, leaving undiminished (or even augmented) the need for a command of basic circuit analysis.

Carrying this thesis a bit further, imagine an engineer educated without regard to specialization in any of the traditional fields, but soundly competent in such fundamental modes of engineering analysis as:

1. Linear circuit theory (applicable to certain cases of heat transfer, fluid flow, and mechanical and acoustical devices, as well as electrical circuits).
2. Nonlinear analysis, including piecewise linear approximations and graphical methods.
3. Field theory, including experimental, graphical, and numerical solutions.
4. Statistical methods.

It is not difficult to visualize an industry program which could build upon such foundations the necessary techniques and application information to produce engineers for effective productivity in the telephone industry or in any industrial environment.

If one recognizes the existence of a long-range trend toward emphasis on fundamental principles and concepts in engineering education (and there is increasing evidence of the acceptance of this philosophy) then industry must indeed assume additional responsibilities in staff development.

Application of Finite Integral Transforms to Analog Simulations

WALTER J. KARPLUS
NONMEMBER AIEE

PREWITT A. STEPHENS, JR.
NONMEMBER AIEE

INTEGRAL transformations are defined by the expression

$$(p)=\int_a^b f(x)K(p,x)dx \qquad (1)$$

where $K(p, x)$ is termed the transformation kernel. Theoretically a wide variety of functions could serve as kernels, and an infinite number of transformations could be generated. However, only a limited number of kernels possess those properties which make their transforms useful for the solution of practical problems.

Most engineers are familiar with the Laplace transform whose kernel is ϵ^{-px} where $p=\sigma+jw$. In this case the limits on the integral are zero and infinity. This transform is, therefore, useful for the solution of problems in a semi-infinite region. Since the time domain in engineering problems has this characteristic, Laplace transforms are particularly useful for the solution of ordinary differential equations in which time is the independent variable.

In treating field problems characterized by partial differential equations, finite integral transforms comprise a valuable tool. As described by Tranter,[1] finite integral transformations are those transforms for which the limits a and b of equation 1 remain finite. These limits are chosen so as to correspond to the co-ordinates of the field boundaries along the independent space variable being transformed. As shown in the Appendix, the kernel $K(p, x)$ can be any function belonging to an orthogonal set. The kernel suitable for any specific problem is determined by the form of the analytical solution of the problem in the co-ordinate system being used. The analytical technique of separation of variables, applicable to 11 different co-ordinate systems,[2] leads to ordinary differential equations whose solutions are usually infinite series.

These infinite series comprise the kernel functions for the construction of the transforms. Thus, for example, in Cartesian co-ordinates sine and cosine transforms are employed; in cylindrical co-ordinates Hankel transforms are used; and the Legendre transforms are applicable to spherical co-ordinates.

Analytical methods for solving field problems are limited to fields having relatively simple geometries. To analyze fields with irregular boundaries, numerical or analog methods must be employed. In this paper the application of integral transforms to facilitate analog simulation methods is considered.

The Finite Sine Transform

When a function $f(x)$, $0\leq x\leq\pi$, can be expressed as the sum of sinusoidal terms in the well-known Fourier Series

$$f(x)=\frac{2}{\pi}\sum_{p=1}^{\infty}\bar{f}(p)\sin(px),\ 0\leq x\leq\pi \qquad (2)$$

then the coefficient $\bar{f}(p)$ of the p th term defines the finite sine transform, where

$$\bar{f}(p)=\int_0^\pi f(x)\sin(px)dx \qquad (3)$$

Equations 2 and 3 are the sine transform pair where equation 3 defines the transform and 2 its inverse.

To find the transform of $d^2\phi/dx^2$

$$\bar{f}(p)=\int_0^\pi d^2\phi/dx^2\sin(px)dx \qquad (4)$$

Integration by parts of equation 4 leads to

$$\bar{f}(p)=[\sin(px)(d\phi/dx)]_0^\pi - p\int_0^\pi d\phi/dx\cos(px)dx \qquad (5)$$

Paper 59-10, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted July 3, 1958; made available for printing November 10, 1958.

WALTER J. KARPLUS is with the University of California, Los Angeles, Calif., and PREWITT A. STEPHENS, JR. is with Hughes Aircraft Company, Culver City, Calif.

Vol.
Pt. 1
1959

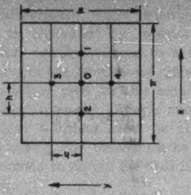

Fig. 1. Finite difference grid in two dimensions

The first term on the right-hand side of equation 5 is zero if $d\phi/dx$ is finite in the interval $0 \leq x \leq \pi$, and further integration by parts leads to

$$(p) = -p[\phi(x)\cos(px)]_0^\pi - p^2\int_0^\pi \phi(x)\sin(px)dx \qquad (6)$$

Now define $\bar{\phi}(p)$ as

$$\bar{\phi}(p) = \int_0^\pi \phi(x)\sin(px)dx \qquad (7)$$

Evaluating equation 6 and substituting equation 7 leads to

$$\bar{f}(p) = p[\phi_{x=0} - (-1)^p \phi_{x=\pi}] - p^2\bar{\phi}(p) \qquad (8)$$

Equation 8 shows that $\phi(x)$ must be known at $x=0$ and $x=\pi$. These are the specified boundary conditions of the problem. If the derivatives are specified at the boundaries, the cosine transform is used instead of the sine transform. If $\phi(x)$ is specified at $x=0$ and $d\phi/dx$ at $x=\pi$, then a special sine transformation is needed.

The Application of the Sine Transform

As a simple demonstration of the use of the sine transform, consider the two-dimensional heat transfer in a rectangular plate. The field equation to be solved is

$$\partial^2 V/\partial x^2 + \partial^2 V/\partial y^2 = (1/k)\partial V/\partial t \qquad (9)$$

The boundary conditions for simplicity are taken to be

$$V=0;\ x=0,\ \pi,\ y=0,\ \pi,\ t>0 \qquad (10)$$

For fields of other dimensions, a simple linear transformation can be employed. The initial condition is taken to be

$$V=V_0;\ t=0,\ 0 \leq x \leq \pi,\ 0 \leq y \leq \pi \qquad (11)$$

First, V is transformed to $\bar{V}$ by means of equations 7, 8, and 10 in order to eliminate $\partial^2 V/\partial y^2$ from the field equation. This leads to

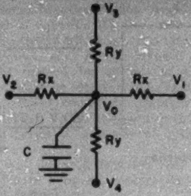

Fig. 2. Typical node of R-C analog for diffusion equation

$$\partial^2 \bar{V}/\partial x^2 - p^2\bar{V} = (1/k)\partial\bar{V}/\partial t \qquad (12)$$

Transforming the initial condition of equation 11 leads to

$$\bar{V}_0 = \bar{V}(x,\ p,\ 0) = \int_0^\pi V_0 \sin(py)dy, \quad t=0,\ 0 \leq y \leq \pi \qquad (13)$$

and from equation 13 the transformed initial condition is obtained:

$$\bar{V}_0 = \begin{cases} 0,\ p=\text{even} \\ 2V_0/p,\ p=\text{odd} \end{cases} \qquad (14)$$

Application of the sine transform to equation 9 has resulted in a new partial differential equation with new initial conditions. The boundary conditions on y could also be transformed, but since they are specified as being zero, they remain zero.

The sine transform is now applied to $\bar{V}'$ to eliminate $\partial^2\bar{V}/\partial x^2$ from equation 12. This leads to

$$d\bar{V}'/dt + (p'^2+p^2)k\bar{V}' = 0,\ p=\text{odd} \qquad (15)$$

where $\bar{V}$ is the doubly transformed variable and p' is transform of x. The initial condition for this equation is found as in equations 13 and 14 and is

$$\bar{V}_0' = 4V_0/pp',\ t=0,\ p,\ p'=\text{odd} \qquad (16)$$

The double application of the sine transformation to equation 9 has reduced this equation to the ordinary differential equation, equation 15. The solution of equation 15 is readily obtained as,

$$\bar{V}' = \frac{4V_0\epsilon^{-n^2kt}}{pp'}\ p,\ p'=1,\ 3,\ 5,\ \ldots. \qquad (17)$$

where,

$$n^2 = p'^2 + p^2 \qquad (18)$$

The final solution is obtained by applying the inverse sine transform equation 2 to equation 17 twice. This leads to,

$$V = \frac{16V_0}{\pi^2}\sum_{p=1}^{\infty}\sum_{p'=1}^{\infty}\frac{\epsilon^{-n^2kt}}{pp'}\sin py \sin p'x \qquad (19)$$

$p,\ p'=1,\ 3,\ 5,\ \ldots$

Analog Solution of the Untransformed Diffusion Equation

The electric analog solution of the diffusion equation 9 can be effected in several ways.[3] Here we will consider the conventional R-C (resistance-capacitance) network analog. The problem defined by equations 9, 10, and 11 may be represented by a 2-dimensional mesh where the spacing between nodes is designated as h.

For any particular node such as node zero in Fig. 1, equation 9 is expressed in finite difference form. This allows one to write the partial derivatives of equation 9 as differences in the temperature T between nodes 1-0, 3-0, etc. So, equation 9 becomes

$$\frac{(T_1-T_0)}{h^2} + \frac{(T_2-T_0)}{h^2} + \frac{(T_3-T_0)}{h^2} + \frac{(T_4-T_0)}{h^2} = \frac{1}{k}\frac{dT_0}{dt} \qquad (20)$$

If temperature T is made analogous to voltage V, h^2 corresponds to resistance, and $(1/k)$ corresponds to capacitance. Equation 20 then becomes

$$\frac{V_1-V_0}{R_x} + \frac{V_2-V_0}{R_x} + \frac{V_3-V_0}{R_y} + \frac{V_4-V_0}{R_y} = C\frac{dV_0}{dt} \qquad (21)$$

where $R_x = R_y = h^2$; $C = 1/k$. Equation 21 is recognized as the Kirchoff's current law equation for a junction of five elements as shown in Fig. 2.

Analog Solution of the Singly Transformed Diffusion Equation

The electrical analog of the transformed equation 12 is constructed in a similar manner to that described previously.

Fig. 7. Electronic analog system for automatic inversion

Vol.
Pt. 1
195

However, this equation has only one space variable x. In finite difference form, equation 12 becomes

$$\frac{(\bar{V}_1-\bar{V}_0)}{h^2}+\frac{(\bar{V}_2-\bar{V}_0)}{h^2}+\frac{(-\bar{V}_0)}{1/p^2}=\frac{1}{k}\frac{d\bar{V}_0}{dt} \qquad (22)$$

where the subscripts refer to the line elements shown in Fig. 3.

The network section for a typical node is derived from equation 22 and is shown in Fig. 4, where

$$R_x=h^2,\ R_0=1/p^2 \qquad (23)$$

and

$$C=1/k \qquad (24)$$

If the network sections of Fig. 4 are placed at each node of Fig. 3; if the two end points are grounded to correspond to the zero boundary conditions; and if the initial conditions are applied as a charge at each node, then one obtains the network shown in Fig. 5 which is the electric analog of equation 12. This network can be used in lieu of the conventional two-dimensional R-C network.

According to equation 23, R_0 is a function of p. It is therefore necessary to construct a new network (or to modify the original network) for each successive value of $p=1, 3, 5, \ldots$ and to record the network node voltages in each case. Since the transformed initial conditions as well as R_0 decrease as p increases, the magnitudes of the node voltages generally become negligibly small after the first few values of p.

To obtain $V(x, y, t)$ from the analog solution $\bar{V}(x, p, t)$ one must use the following inversion equation:

$$V(x, y, t)=\frac{2}{\pi}\sum_{p=1}^{\infty}\bar{V}(x, p, t)\sin(py)\ p\text{–odd} \qquad (24A)$$

This inversion process may be done analytically or by using the analog technique described in the following section.

Analog Solution of the Doubly Transformed Diffusion Equation

Equations 15 and 16 imply the solution of an ordinary differential equation. The two successive applications of the sine transform have entirely eliminated the space variables. The two-dimensional diffusion equation therefore, can be solved by an electronic differential analyzer using only one integrator as shown in Fig. 6. The output of this circuit is proportional to $\bar{V}'$. The doubly transformed $\bar{V}'$ must then be inverted to find the temperature V, according to

$$V(x, y, t)=\frac{4}{\pi^2}\sum_{p=1}^{\infty}\sum_{p'=1}^{\infty}\bar{V}'(p, p', t)\times \sin(py)\sin(p'x) \qquad (25)$$

where p, p' are both odd integers.

The summation required by equation 25 may be performed on an electronic analog computer. If a separate integrator is used for each combination of p and p', and if all their outputs are applied to a summing circuit after appropriately scaling each output by $\sin(py_0)\sin(p'x_0)$, the output of the summer is $V(x_0, y_0, t)$. Such a circuit is shown in Fig. 7. Since both p and p' range from one to infinity, it is obviously impossible to treat all combinations of these parameters. However, since the initial conditions on the integrator are divided by pp', the voltage outputs of the integrators rapidly converge to zero as either p or p' becomes large.

This summing circuit only produces a solution at one point (x_0, y_0). A similar circuit would be needed for every other point desired. One could also reset the parameters and make additional runs to obtain additional points. This requirement of extra equipment or additional runs tends to offset some of the advantages of this technique.

Conclusions

The application of the sine transform to a simple field problem governed by the diffusion equation has been demonstrated in the foregoing. The method is readily extended to other partial differential equations and other co-ordinate systems. From the point of view of electric analog simulation, this method effects a considerable saving in equipment. A three-dimensional system requiring hundreds or thousands of resistors and capacitors can be reduced to a two-dimensional or one-dimensional system. A price must be paid for this economy in equipment, however. A large number of parametric solutions must be obtained on the analog, and these must be scaled and summed to obtain the final inverted solution.

Appendix

The General Finite Integral Transformation

Since a finite integral transformation is derived from an infinite series of orthogonal functions, it is possible to define a general expression for a finite integral transformation in terms of a general orthogonal function. After this general expression is derived, the well-known transforms such as the sine and cosine transform can be obtained readily.

Let us define an infinite series of functions

$$\phi_1(x),\ \phi_2(x),\ \ldots\ \phi_n(x),\ \ldots \tag{26}$$

which has the following properties

$$\int_a^b \rho(x)\phi_m(x)\phi_n(x)dx \begin{cases} =0, & m\neq n \\ \neq 0, & m=n \end{cases} \tag{27}$$

If the series equation 26 has the properties specified in equation 27, the series is said to be orthogonal with respect to the weighting function, $\rho(x)$ in the interval (a, b). A series defined by $\sin(nx)$ or $\cos(nx)$, where n takes on integer values and $\rho(x)$ is unity, satisfies condition equation 27 in the interval 0, π. So the well-known Fourier Series is a series of orthogonal functions.

One can define a function $f(x)$ in the interval a to b by an appropriate infinite series as follows

$$f(x)=\sum_p A_p\phi_p(x),\ a\leq x\leq b \tag{28}$$

In order to determine A_p, multiply equation 28 by $\rho(x)\phi_q(x)$ and integrate over the interval a, b.

$$\int_a^b \rho(x)f(x)\phi_q(x)dx = \sum_p A_p \int_a^b \rho(x)\phi_p(x)\phi_q(x)dx \tag{29}$$

From equation 27 it is seen that all terms are zero except when $p=q$. So, equation 29 becomes

$$A_p=\frac{\int_a^b \rho(x)f(x)\phi_p(x)dx}{\int_a^b \rho(x)\phi_p^2(x)dx} \tag{30}$$

Substitution of equation 30 into equation 28 leads to,

$$f(x)=\sum_p \frac{\phi_p(x)\int_a^b \rho(x')f(x')\phi_p(x')dx'}{\int_a^b \rho(x')\phi_p^2(x')dx'} \tag{31}$$

where $a\leq x\leq b$.

Now, if the numerator of equation 30 is defined as $\bar{f}(p)$, and inserted in equation 31, one obtains the following transform pair:

$$\bar{f}(p)=\int_a^b \rho(x)f(x)\phi_p(x)dx \tag{32}$$

$$f(x)=\sum_p \frac{\bar{f}(p)\phi_p(x)}{\int_a^b \rho(x')\phi_p^2(x')dx'},\ a\leq x\leq b \tag{33}$$

Equations 32 and 33 are the general expressions defining a finite integral transformation pair.

Computational and Experimental Techniques in Nuclear Reactor Design

W. F. WITZIG
MEMBER AIEE

M. R. STUART
NONMEMBER AIEE

L. O. HERWIG
NONMEMBER AIEE

THE PURPOSE of this paper is to discuss a nuclear design technique for a nuclear power reactor. It is felt that this area of reactor design is not as well-known in the engineering profession as, for example, power plant systems or control systems.

The design of a nuclear power plant begins with a list of technical objectives which are arbitrarily divided into two groups, engineering design and nuclear design, as shown in Fig. 1. Technical objectives include such items as size, power capacity, core life, methods of reactivity control, materials, and other items such as operating temperatures and temperature coefficients of reactivity that are more closely related to the plant system.

For the purposes of this discussion, only the right-hand branch of Fig. 1, the nuclear design, will be considered. It has been divided into two activities: 1. experimental, and 2. analytical. The experimental activity involves a critical facility and its associated program. The experimental facility is described in a paper by E. S. Lembersky.[1]

To help establish what is meant by nuclear design, it is necessary to resort to an illustration of the design sequence; see Fig. 2. This chart not only shows the sequence of events, but helps establish the relationship between the analytical and the experimental activities. Knowing the nuclear core objectives, the next step is to develop an elementary design model. Such a model is generally very simple; the core inventory is assumed to be homogeneously distributed throughout the volume. Employing this model, it is customary to study the reactivity or effective neutron multiplication of various core inventories.

The inventory variables include the quantity of fissionable material, structure, moderator, and perhaps more important, the quantity of poison or control material. Evaluation of the results leads to a preliminary design which includes such items as the distribution of the nuclear materials, the geometry, the number and the distribution of the reactor control rods, the size of the reactor core, and the metal-to-water ratio. The preliminary nuclear design is closely related to the engineering design, as indicated in Fig. 1. However, this discussion concerns only the nuclear aspects of this design.

At this point both the experimental and the analytical activities can proceed in parallel. Close liaison is required between these two efforts.

Paper 58-1315, recommended by the AIEE Nucleonics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Pittsburgh, Pa., October 26-31, 1958, and re-presented at the Winter General Meeting, New York, N. Y., February 1-6, 1959. Manuscript submitted August 25, 1958; made available for printing December 3, 1958.

With a somewhat limited ability to predict criticality of the reactor the primary emphasis of the experimental program is to provide measurements which can be compared to calculations based on the nuclear design model. Criticality is the characteristic of a reactor core which describes the core's ability to sustain a nuclear chain reaction. In the general case the experimental program is directed at studies of the critical assembly, which are described in the section dealing with "Experimental Methods in Reactor Design." In addition to the uncertainties of the nuclear model for predicting criticality of this complicated assembly of nuclear materials, there may be uncertainties in the values of the constants which are used in the model. Examples of some of these constants are the neutron cross section of the products generated as a result of the fission process, the resonance absorption in U-238 which leads to the production of plutonium, and the product of the xenon fission yield and neutron cross section. A portion of the experimental program is often devoted to measuring the quantities associated with the calculation of reactor constants.

In parallel with the experimental effort the analytical work proceeds, using a model more nearly representative of the reactor core than the early elementary nuclear model. Such a model begins to take into account (with two-dimensional analysis) the core heterogeneities, the geometry of control rods, and the distribution of nuclear fuel.

Having at this stage both experimental and analytical work of sufficient detail, a check of the nuclear model is performed. Then it is possible to refine the nuclear model so it is a more exact representation of the power reactor. These refinements then lead to both detailed experimental programs and analytical programs, which are again woven into a final model check. At this point we then can move from the final model check into a final determination of the nuclear inventory.

It is desirable to continue the experimental work on what might be called core start-up tests, which involve such items as biological shielding studies, and neutron source strengths for start-up. If there has been some operating experience with this type of reactor, it is possible at the final nuclear inventory stage to initiate core construction. However, the operating characteristics as a function of lifetime of the core may well be predicted prior to the initiation of core construction. Examples of these operating characteristics are the criticality of the core as a function of lifetime and the power distributions throughout this lifetime.

In the second section of this paper the nuclear model is examined in greater detail. In the third section the computation techniques used in the analytical program to perform nuclear model checks and to give the engineering designer his required information are examined. In the fourth section, the experimental program is reviewed, showing typical experimental techniques involved in producing experimental data. In the fifth section of the paper, some thoughts about the future role of the computational and experimental techniques in reactor design are discussed.

Description of a Nuclear Design Model

The discussion thus far has been sufficient to point out that a nuclear reactor has a variety of characteristics, not all of which contribute to the peace of mind of the reactor designer. Some of the more objectional ones we have to live with, others we are able to circumvent, while it is possible to exploit still others to meet design objectives. The purpose of this section is to pull these characteristics together in a conceptual picture, which we choose to call the nuclear design model. Every designer, whether he be a mechanical, thermal, or hydraulic engineer or a physicist, has in his mind a picture of the reactor. More

specifically he thinks of the particular aspects of the reactor in terms of the characteristics and qualities for which he is responsible. The mechanical engineer, for example, may view the reactor as a series of masses, spring-connected, each with a certain size, strength, and natural frequency. With this picture, or model, he then proceeds to evaluate its characteristics through a mathematical representation, which allows quantitative evaluations to be made and specifications to be determined. The quantitative results are then compared with the objectives of the design. Most frequently, the peculiar requirements of a given reactor design call for devices which are developmental in nature. Thus the engineer must supplement his calculations with tests involving mock-ups or models of the proposed design. The discussion here, though elementary, is to remind the reader that even today, with a discipline as old as that of mechanical engineering, often a semi-empirical approach is necessary in reactor design. This is due to in part to the stringent requirements of reliability but also to the lack of accumulated engineering experience in this rather new field.

NEUTRONS, ATOMS, AND FISSION

As one moves to the reactor physics aspect of reactor design, a situation similar to that of the mechanical designer is found. From the physics or nuclear design standpoint the reactor is viewed from a different conceptual picture, but the problems of design are of comparable difficulty. One must design a core which is producing heat by a nuclear reaction involving fissionable material, supported by structural material in a moderating environment, and permeated by a cloud of neutrons. Neutrons are infinitesimal particles of matter which are able to penetrate large thicknesses of ordinary material. The presence of neutrons in the nuclei of almost all materials contribute to their stability. With specific nuclei, however, an excess of neutrons can exert very disruptive forces. These forces cause the nuclei to fission, i.e., split into parts having large kinetic energy, which is shared with the environment. The fundamental problem of the reactor physics designer is to bring together many neutrons and fuel nuclei in such a manner as to cause a controlled release of this energy.

NEUTRON CYCLE

Consider a single fission neutron from its birth to its death (absorption) or escape from a reactor core. A fission neutron is born at a relatively large average energy (about 2 million electron volts) and is called a fast neutron. It has an average speed of about 10,000 miles per second. As the neutron moves swiftly through the core, it collides with atoms of the material in the reactor. These collisions may scatter or absorb the neutron. In a water-cooled reactor one of the principal neutron scattering processes is that with the hydrogen in the water. In this process the neutron loses some of its energy to the hydrogen atom at each collision. This sequence of energy loss is called the slowing down or moderation of the neutrons. Eventually, a neutron loses most of its speed and thereby increases its chances for interaction with fuel nuclei, since it spends a longer time in the vicinity of the fuel nuclei when it passes by at a lower speed. The fact that a neutron is absorbed by fuel and the fission process initiated, is the basis for the chain reaction which makes nuclear power feasible.

The fuel usually splits into two fragments, each with considerable kinetic energy which manifests itself as heat. In addition to the fission fragments, approximately 2.5 neutrons are born (represented by the symbol ν) in the fission of U-235. Thus, in analogy with chemical processes, the neutron acts as a catalyst for the generation of heat, and, in addition, reproduces itself by a factor of 2.5.

Two categories of neutrons are identified with the fission process: 1. neutrons released at the instant of fission of a fuel atom, called prompt neutrons, and 2. neutrons emitted by certain radioactive fission fragments as long as several minutes after the fission fragments are created, called delayed neutrons. Of the approximately 2.5 neutrons born in each fission process, the delayed neutrons make up less than 1%. However, it is these neutrons which exert a damping action upon the kinetic response of a reactor and ease the control engineer's problems.

If one were to follow these fission neutrons as they slowed down, it would be found that some escape the reactor core entirely and some interact with materials other than fuel. These losses of neutrons do not contribute to the production of power. However, if one of these 2.5 fission neutrons eventually slows down and is absorbed in fuel to cause fission, the process is self-sustaining and is called stationary, since the total number of neutrons remains constant in time. Such a condition of the reactor is called the "critical state." Fig. 3 illustrates in a simplified manner the events occurring following the absorption of 100 slow neutrons in the fission process. This results in the release of approximately 250 fast neutrons, some of which in the process of slowing down are absorbed or escape the core. The remaining neutrons are then available to repeat the process.

The time from neutron birth through absorption to the re-emission of a neutron in a subsequent fission process is called the neutron generation time. This cycle occurs on the average of 10,000 to 100,000 times per second. The ratio of the number of neutrons released in the fission process at a given time to the number released in succeeding generations of fission neutrons is called the effective multiplication constant, k_{eff}. If k_{eff} equals 1, the system exactly reproduces itself and is stationary. If k_{eff} is greater or less than 1, the system will increase or decrease, respectively, in power. The percentage deviation, $(k_{eff}-1)/k_{eff}$ is called the reactivity ρ. The reactivity ρ is zero for the critical state $(k_{eff}=1)$ and greater or less than zero as k_{eff} is greater or less than unity. The principal problem of the nuclear designer is to control both the competition between the various core materials for the absorption of the neutrons and the neutron escape from the reactor.

NEUTRON FLUX

To determine quantitatively the nuclear characteristics and to obtain the design objectives of the reactor, a mathematical description is necessary. The neutrons in the core are treated in the same manner as a diffusing gas, with the additional feature that absorption and creation of the neutrons are taken into account. Consider an elementary volume of the core in a stationary system; the leakage plus the absorption in the elementary volume must equal the source of neutrons. Expressing this balance mathematically gives rise to a set of coupled differential equations. A solution to this set of equations, with the proper boundary conditions, represents the neutron flux as a function of position in and around the reactor core. This neutron flux, commonly represented by the symbol ϕ, is a quantitative measure of the neutrons present at a particular point in the reactor core at a given instant of time. With this knowledge it is possible to calculate the expected rate of energy release, biological shielding requirements, and control requirements, all of which are reactor design objectives.

HETEROGENEITIES

As mentioned previously, two features of the reactor which contribute to its operation are: 1. slowing down of fast or energetic neutrons and 2. the fission process itself with the accompanying release of extra neutrons. Since most of the slowing down takes place in the moderator, distribution of water in the reactor is of importance in calculating power distributions. For instance, there are usually large regions of the core in which control elements are physically moved. This is illustrated in Fig. 4(A). The rather simple geometry illustrates a cross-shaped control rod surrounded with core structure and fuel. In Fig. 4(B) the number of regions is increased, giving more detail to the representation. When the control elements are removed from the core a relatively large volume of water (the moderator in pressurized water reactors) occupies their former position. Consequently, unless precautions are taken, the power generated in fuel in the immediate vicinity of the control rod channels is increased (due to the slowing down properties of the water). This behavior is called water-hole peaking and must be minimized to reduce nonuniform power generation. The power generated in the fuel plates next to the control rod channels is frequently the limiting factor in meeting thermal design requirements.

DESCRIPTION OF THE NUCLEAR DESIGN MODEL

Now that a few details of the core design have been described, a model that may be used to investigate the characteristics of a reactor is discussed. Two questions shall be asked: 1. What is required from the model? 2. What must the designer specify to conduct the calculations for a given model? In answer to the first question, the following are needed: 1. a materials inventory which gives a specified lifetime, 2. the number, size, shape and effect of control rods, 3. spatial power distribution throughout the core lifetime, and 4. the effect of changes in temperature upon the neutron multiplication process. To obtain answers to the second question, a designer must specify: 1. the geometry and the mode of depletion of fuel and poisons in the core; 2. the number of groups of neutrons with specified energies; and 3. values of the nuclear parameters which are required by the mathematical description of the core. The last is referred to as the reactor constants.

All characteristics of the reactor core depend to some extent upon the distribution of fuel within the core volume. Consequently, during the depletion process, the characteristics of the core change. The principal problem of a nuclear designer is to calculate the changing distribution of the fuel and burnable poisons, and in turn, the changing characteristics of the core. However, for estimates of the core performance throughout lifetime, it is convenient in the preliminary studies to neglect the spatial variations of the fuel and carry out the calculations as if the fuel were uniformly distributed. This model of the core is the first of two general classifications of nuclear design models, namely, the spatially uniform depletion model. This model is used to obtain the initial nuclear inventory, as given in Fig. 2 in the nuclear design sequence. An illustration of the spatially uniform depletion model is shown in Fig. 5.

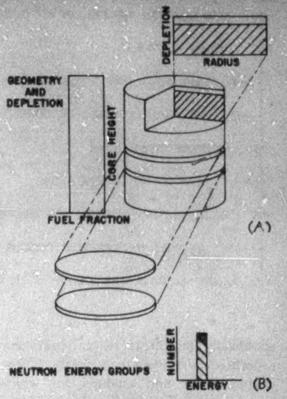

Fig. 5. Nuclear design of spatially uniform depletion model

Constants:*	
Absorption	Maxwellian
Fission	Maxwellian
Leakage	Constant

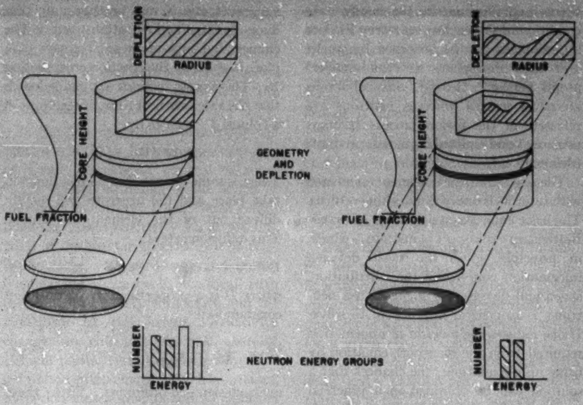
* For purposes of simplicity some liberty has been taken in assigning the type of constant to each model.

For the initial calculations to determine the preliminary estimate of the nuclear inventory, it is usually sufficient to assume a rather simple geometry for the core, that of a right circular cylinder, and in addition to assume that all materials (fuel, poisons, and core structure) are distributed homogeneously throughout this region. This is illustrated in Fig. 5(A). In addition, it is usually assumed that the calculations can proceed using the average properties of the group of neutrons whose energies are distributed like those of gas molecules in thermodynamic equilibrium at the particular temperature of the core. Therefore, this distribution of neutron energies is essentially a one-group representation. This is illustrated in Fig. 5(B). Consequently, the constants listed in Fig. 5 are calculated assuming the neutron energy distribution is the same as that of a gas at this particular temperature and, therefore, the Maxwellian averages are used. It should be pointed out that this model is only sufficient to determine an estimate of the materials inventory which will result in

Vol. 7
Pt. 1
1959

a given lifetime for the core. Neither power distributions nor changes in characteristics of the core parameters with lifetime can be calculated. In order to calculate these one proceeds in the nuclear design sequence to the revised nuclear inventory state; see Fig. 2.

At this point in the sequence use is made of some models which are characterized by the title of nonuniform depletion models. There are principally two types used at the present. The first type, Fig. 6(A), takes into account the depletion of fuel and poisons in the reactor with lifetime over one dimension of the core.[2] Usually this is in the axial direction. In this particular model the core constituents are still assumed to be distributed at the beginning of life in a homogeneous manner. Then the depletion calculations are initiated, and the core is divided for the purposes of calculation into a series of axial segments, somewhat similar to a stack of poker chips. The history of each of these chips is followed throughout the core lifetime, with the result that, as the depletion proceeds, these chips will contain differing amounts of fuel and poisons. In these studies, the energy distribution of the neutrons is extended to either two or four groups. With this extension, both in the spatial distribution of fuel and number of neutron energy groups, it is now possible to obtain estimates of the variation of certain properties of the core throughout lifetime. In addition to a more accurate estimate of the core lifetime for a given initial nuclear inventory, one can obtain axial power distributions and preliminary estimates of the control requirements necessary to meet the over-all design objectives. Also, one obtains reasonable estimates of the nuclear characteristics of the core with this one-dimensional depletion model, and information is obtained which is passed to the thermal and hydraulic engineers. These studies then result in a sufficient body of information to continue the nuclear design revisions. The principal advantage of this model is that it gives information sufficient for an estimate of the relative merits of several proposed designs, but is still simple enough to use in survey-type calculations.



(A) (B)

Fig. 6. Nuclear design of nonuniform depletion model

A—One-dimensional synthesis
B—Three-dimensional synthesis

Constants	Slow Neutron Group	Fast Neutron Group
Absorption	Maxwellian	Neutron Slowing Theory (reference 5)
Fission	Maxwellian	Fission permitted
Leakage		Varies with lifetime

When the final nuclear inventory is established the next stage of the design is to obtain the detailed operating characteristics of the core, both nuclear and engineering, as a function of its lifetime. This is done with a nonuniform depletion model, illustrated in Fig. 6(B). Use is again made of the concept of stacking horizontal segments of the core to obtain a nonuniform depletion of fuel throughout lifetime. However, the additional feature of the nonuniform depletion of the fuel and poisons throughout each axial segment is taken into account. The geometrical representation of the reactor in the horizontal plane is done in as much detail as possible, within the scope of the computing facilities. With these axial segments again superimposed, one obtains a three-dimensional representation of both power and fuel distributions throughout lifetime. This model, at the present time, is too complicated to use as a survey tool and is used only with the final nuclear inventory. To use this concept effectively, it is usually assumed that the neutron energy spectrum is composed of two energy groups. This assumption accounts for fission both in the fast and slow groups, with the resultant better estimate of the power distribution, and yet is simple enough to be used conveniently. In addition, one represents explicitly the control elements in the core and obtains a more accurate estimate of their effectiveness.

The preceding discussion outlined the various nuclear design models utilized as the design proceeds from the preliminary design, using a spatially uniform depletion model, to the final specifications of the core characteristics as a function of lifetime, using the three-dimensional superposition model. At each stage of the design sequence, the models are used to calculate the results of experiments performed with the critical assembly. These so-called "model checks" result in modifications of the nuclear inventory. The computing techniques for evaluating these models are discussed in the following section.

Computational Techniques

How physical concepts are fashioned into mathematical equations, and how solutions to these equations are obtained will now be indicated. The results of the analytic effort are phased with the experimental program to evaluate and develop the nuclear design model as indicated in Fig. 2 and further discussed in the section on "Experimental Techniques."

The main features of the mathematical treatment of reactors are taken directly from classical statistical mechanics, mainly the kinetic theory of gases. These include number density, mass flow, and the concept of scattering cross section. There are several distinct differences, however, between classical atoms in thermal equilibrium and the steady-state condition in the nuclear reactor. First of all, neutrons can be absorbed by nuclei and thus disappear, whereas classical atoms persist. Second, classical atoms are never created, whereas neutrons are released in the fission process (prompt neutrons) and emitted by fission products (delayed neutrons).

The mathematical treatment connected with reactors is one of diminishing returns. The basic equation, a linearized Maxwell-Boltzmann transport equation, which, in principle, gives the most detailed information concerning the distribution, speed and direction of flight of the neutrons, is in general impractical to solve. If one reduces the amount of information required from the transport equation by using approximations, the chances that a solution can be obtained in a practical manner are improved. It is, nevertheless, still necessary to utilize digital computers to solve these approximate equations in a reasonable length of time.

To illustrate some of the problems faced by the reactor designer, one of the main analytical problems is examined. If there are enough neutrons present in a reactor for statistical averages to be valid, then it is possible to use a point function, called the neutron flux, to calculate power distributions, flux peaking factors, and the variation of reactor control with changes in temperature and uranium depletion. For instance, the slow neutron flux would be that group of neutrons having speeds up to a certain upper limit, at a point within or about the reactor. Likewise, the second group of neutrons (fast groups) have speeds above the upper limit for the slow group.

The number of neutrons dn within and passing through a volume dV in a time dt is given by

$$dn = \phi/v\,dV\,dt \qquad (1)$$

where ϕ is the neutron flux and v is the average speed of the neutrons. If the reactor is operating at a steady rate, ϕ is only a function of position within the reactor. Strictly speaking, the flux ϕ is to be interpreted, after proper normalization, as the probability density of a neutron being present in a particular volume, whereas the actual number of neutrons present in a small volume fluctuates from time to time. If enough neutrons are present, however, these statistical fluctuations are very small.

As these neutrons pass through matter, there is a certain probability that various reactions take place between the neutrons and the atoms of matter present. The neutrons may be absorbed to produce very energetic X rays or they may produce fission in fuel atoms, etc. The chance that any of these processes take place is given by the reaction cross section Σ. These cross sections are defined such that the rate, per unit time, of reactions in a volume dV is given by

$$\text{Reaction rate} = \Sigma\phi\,dV \qquad (2)$$

There is some chance that no reaction will take place and the neutrons will merely diffuse out of the element of volume. This diffusion rate is:

$$\text{Diffusion rate} = -D\nabla^2\phi\,dV \qquad (3)$$

where D is a proportionality or diffusion constant and

$$\nabla^2\phi = \frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial y^2} + \frac{\partial^2\phi}{\partial z^2} \qquad (4)$$

in cartesian co-ordinates. With these results, it is possible to write a representative equation in three dimensions, which exhibits the neutron economy under steady-state conditions.

$$(\underbrace{-D\nabla^2\phi} + \underbrace{\Sigma\phi} - \underbrace{S})\,dV = 0 \qquad (5)$$

$$\underbrace{\text{Leakage} + \text{Absorption}}_{\text{Loss}} = \text{Source}$$

In the two neutron group treatment there are two flux functions, ϕ_1 and ϕ_2, one for each neutron group. The equations which these flux functions satisfy are related, since the source for each group is proportional to the flux of the other group. The diffusion equations are

$$D_1\nabla^2\phi_1 - \Sigma_1\phi_1 + v\Sigma_2\phi_2 = 0 \qquad (6)$$

(thermal fission only)

$$D_2\nabla^2\phi_2 - \Sigma_2\phi_2 + \Sigma_1{}^R\phi_1 = 0 \qquad (7)$$

Equations 6 and 7 are approximated by a set of finite difference equations, with the result that a set of algebraic equations must be solved instead of a set of differential equations. This is done by numerical methods using various iterative schemes.[3] Since, in principle, an iterative scheme only converges after an infinite number of iterations, some error is introduced in the solutions by using only a finite number. The degree of convergence is controlled by the reactor designer on the basis of required precision, computing time, and cost.

There are at least three main areas of uncertainties in the analytic studies associated with reactor design: 1. the use of a group diffusion model instead of the more rigorous transport theory, 2. the fact that the reactor cross sections and diffusion coefficients may have large uncertainties, and 3. the presence of approximations in the numerical solution of the diffusion equations.

Examine a typical nuclear design problem in which it is desired to know the flux distribution along the radius of the core and compare the solution obtained by hand and by digital computer. A typical reactor design problem would involve something on the order of 90 to 100 points within the reactor and 40 to 50 points in the reflector at which it is desirable to find the flux. The solution to this problem requires something of the order of 10^8 mathematical manipulations to solve the difference equations. A girl at a desk-calculating machine can complete about six operations per minute. At this speed it would require something like 20 years to complete this problem, working 24 hours a day. By comparison, a modern high-speed digital computing machine would require only 10 minutes to solve the same problem, with a much higher probability of obtaining the correct answer.

An analogous problem exists in the study of load flow in an electric power network. Such a problem might involve a network having 100 nodes at which we wish to know the flow of real and reactive power. The solution of the simultaneous equations involved requires about the same time on a digital computer as the above nuclear design problem.

Experimental Methods in Reactor Design

Critical assemblies of reactor materials have played an important role in the nuclear design of pressurized water reactors. These assemblies serve to validate nuclear models and provide core startup data, measurements of reactor constants, and operating experience. Such assemblies may be arbitrarily classified as engineering mock-ups, clean criticals, and prototypes. An engineering mock-up is one whose nuclear characteristics correspond closely to the characteristics of the power reactor, except for operating conditions of temperature, pressure, and power. Construction is economical in time and costs, and core arrangement is flexible for study of parameter and design changes.[1] A clean critical assembly incorporates the same advantages in time, cost, and flexibility, and is specifically designed to measure particular reactor parameters with configurations closely applicable to the analytical model. These two types are designated as flexible critical assemblies. A prototype power reactor is an exact reproduction of the design and is quite inflexible with regard to changes in design. Experimental methods can be applied to each of these assemblies to obtain design information. An experimental method good for one may not be applicable for the other types. The discussion of experimental methods will deal largely with the use of a flexible critical assembly for the nuclear design of pressurized water plants.

The critical is constructed from small unitized core materials, and is made to look as much like the power reactor core as is practical. The nuclear design model is checked by this critical near room temperature, at low power, largely at the start of core life (no uranium depletion), and for a wide range of the core parameters.

Quantities which can be measured include critical mass of fuel materials, power distribution, temperature coefficient of reactivity, reactivities with control elements in various configurations, and effects of core and reflector materials. In addition, the critical assembly provides engineering information which includes studies of startup instrument response relative to startup neutron source strength, core startup characteristics, and biological shielding characteristics.

In addition to the flexible critical type of experiments, there are varieties of critical experiments directed at the understanding of the basic nuclear parameters incorporated in the nuclear design model. Some of the nuclear parameters of interest to the nuclear design model include measurements of the stable fission product cross section, xenon transient characteristics, energy distributions of neutrons in the core and the shielding around the core, activation of the shielding or coolant materials, and macroscopic cross section changes of fuel and poison as a function of depletion.

TWO PHILOSOPHIES IN THE OPERATION OF CRITICAL ASSEMBLIES

Reactivity changes in a critical assembly may arise from a large number of sources, e.g., movement of control elements and changes in fuel and poison loading or distribution, in temperature, in core metal-to-water ratio, in core or reflector structural materials, in core geometry, in power, etc. Two operational philosophies can be pointed out in the use of critical assemblies to determine reactivity changes during design studies. First, reactivity differences are measured in terms of position changes of calibrated control elements required to maintain the reactor critical, or in terms of the rate of change of the reactor power as a function of time (period measurements) following a calibrated control element position change. Second, the reactivity changes are measured in terms of a quantitative change of nuclear materials in the core to maintain a critical reactor with no change in the position of the control element.

In the first operational philosophy the control reactivity in many critical experiments consists of control elements in the referenced design or the height of the water moderator. Under these conditions the excess reactivity k_{ex} at the disposal of the reactor operator can be relatively large. Excess reactivity is defined as that above $k=1$ (or critical) with the control rods fully withdrawn and the moderator at full height. Reactivity changes are calculated from the control element position and the reactivity worth per unit position change, which is obtained by period measurements and an equation relating period to reactivity (the in-hour equation).

In the second operational philosophy, reactivity control in critical experiments often consists of auxiliary control rods whose effects are not part of the design study. The reactor is maintained critical by the auxiliary control rods, which are largely removed from the fuel region and whose reactivity effects are small and accurately known. An experimental change in core reactivity is measured in terms of the reactivity worth of a quantity of the nuclear material. This reactivity worth is measured by several methods, including period measurements or subcritical counting rate measurements. If only the auxiliary rods can be moved during operations at criticality, the excess reactivity at the disposal of the operator is only slightly greater than zero. The number of rod withdrawal mechanisms required for operations is small even for large cores with many design rods.

In the experimental methods to be discussed, the two operational philosophies have been combined to obtained design data. All the design rods can be moved during operations at criticality. However, part or all of the design rods can be designated as auxiliary rods, if desirable, and the amount of nuclear material adjusted to measure changes in reactivity. Occasionally, when all design rods are required to be all or partially inserted in the core for an experiment, auxiliary rods are added.

The following classification of experimental methods is chosen arbitrarily:

1. **Critical mass is that quantity of fuel and poison material, which, in conjunction with the reactor structure and moderator, is capable of maintaining a constant power level without an external source of neutrons.**
2. **Reactivity changes or changes in the neutron multiplication constant.**
3. **Neutron flux distribution shows the density of neutrons as a function of position throughout the volume of the core, and is called a power distribution if the fuel loading is uniform.**

Data concerning many reactor parameter may be obtained from a combination of these methods.

CRITICAL MASS METHODS

Many characteristics of a critical assembly are calculated in terms of the configuration and quantity of fuel and poison materials in the core. In particular, the quantity of nuclear fuel or posion material for a given critical configuration can be measured accurately and compared with analytical calculations. The poison material is that neutron absorbing material which is introduced into the reactor for reactivity control rather than for cooling or structural reasons.

One of the first checks of a nuclear design model is a comparison of the calculated and experimental critical masses for a rod-free critical assembly, a clean critical assembly. It is advantageous to work with a fuel element structure as nearly like the power reactor core as is possible, retaining flexibility for changes in nuclear inventory. The experiments may range from relatively simple and homogeneous structures to complex heterogeneous types. The models used to explain the characteristics must also incorporate these heterogeneities; see the section on "Description of a Nuclear Design Model."

The ability of the nuclear design model to include the effects of control rods can be checked by observing the critical mass as a function of control rod position in the core. Calculation of rod effects, particularly for cores containing large numbers of control rods, are simplified by obtaining critical masses of fuel and poison for combinations of design rods either fully in or fully withdrawn from the core. Measurement of the critical mass is an example of the second operational philosophy. The experimental test is a form of a null measurement to obtain $k_{ex}=0$.

REACTIVITY CHANGES

Critical mass measurements require equilibrium power conditions, whereas the reactivity measurements depend on transient behavior of reactor power (reactor period). An equation known as the in-hour equation relates the period and reactivity. The reactivity calculated from this equation depends upon the yield, the lifetime, and the effectiveness of delayed neutrons relative to the prompt neutrons. There are variations in delayed neutron parameters among nuclear fuels, and the effectiveness also varies with reactor configuration. Corrections for these variations can be calculated and applied to the experimental data.

Period measurements are used to determine the differential reactivity worths of control elements, fuel poison, and moderator height. Also, period measurements are basic to measuring changes in reactivity worth induced by placing a sample of material in a reactor core and by changing reactor temperature.

The differential reactivity worths of control rods and moderator height are obtained as follows. First, the reactor power level is stabilized or the period is determined for a given reactor configuration. Next, the control rod or moderator height is changed an accurately determined amount while holding other reactor parameters constant. A new period is then measured. Knowing the periods, the associated reactivity change can be calculated. The differential worth may be found by dividing the change in reactivity by the change in height, thus calibrating the control rod or moderator.

The reactivity worth of fuel or poison material is obtained by altering the material in the core by a known amount and observing the change in critical position of a calibrated control rod or in a reactor period. The temperature coefficient is measured by noting the position of a calibrated rod or the reactor period as a function of reactor temperature.

NEUTRON FLUX DISTRIBUTIONS

Experimental measurements of the neutron flux distributions in a reactor core are compared with those predicted by the nuclear design model. In addition the effects of the reflector around the reactor core and the shutdown reactivity (all control rods in the core) can be determined. The neutron flux distributions also help verify calculations of heterogeneity effects in the core.

Flux distributions can be measured by a variety of materials which become radioactive upon the absorption of a neutron. They must have a sufficiently long half-life so the induced radioactivity can be counted in a nuclear counter after the irradiation. Some flux-plotting materials which are commonly used in critical assemblies are enriched uranium, manganese, dsyposium, gold, and indium. These materials are placed in the core in the form of wires and foils.

Small counters containing special nuclear materials are also used to obtain neutron flux distribution. In these counters the neutrons are absorbed by the atoms of the material to produce energetic nuclear particles. These particles are detected by the counter and recorded in an electronic counting system. The number of pulses is proportional to the number of neutrons which are present at the location of the nuclear material.

Future Role of These Techniques in Reactor Design

In spite of the obivous risks in trying to predict the future in such a new field as reactor design, the authors feel compelled to give a brief discussion in this area. First consider analytical techniques. The goal of these techniques is to reduce the amount of experimental and analytical work required in future reactor designs. The ultimate dream of the designer is to develop the nuclear model and the calculational techniques to a point where experimentation only proves the validity of the techniques and does not contribute anything new. It may be possible to accomplish sufficient progress over the next decade, for pressurized water reactors, that our analytical ability alone will be sufficient for reactor design. How can this be brought about? The digital computer and our nuclear design model will be refined so the problems of transport theory can be reduced by experience and empirical techniques to a state where they will be recognized as engineering problems.

This should not be interpreted as meaning that no experimental work will be necessary a decade from now. Obviously the basic concepts of reactors will need to be explored, just as such concepts are in the electrical industry. Today, the designers are trying to understand the phenomena involved. As they progress up the road to greater refinement, the critical experiments, the engineering mock-up, for example, may well develop into something like a reactivity laboratory. In such a laboratory it will only be necessary to study design details, some unusual phase of a control rod design, or perhaps a unique method of reactivity control. In such a reactivity laboratory, designers would no longer need such things as the clean critical experiment.

Another function which may well develop in this laboratory of the future is reactivity adjustment or shimming. When reactor design involves more than just the design of a single unit, that is, more of the mass-production type of manufacture, it may be economical to adjust the reactivity of a core after it has been produced. To accomplish this, the addition of fuel or nuclear poisons in specific locations in the core designed to accommodate them, may be one of the more important activities in this reactivity laboratory.

Reactor physics experiments utilizing clean critical assemblies, irradiation facilities, electro-nuclear machines, kinetic experiments, and neutron spectroscopy will provide the fundamental knowledge required to simplify reactor design techniques. It is probable that design techniques unknown today will evolve from the understanding gained from the research in the foregoing fields.

With the possibility of space travel becoming more realistic, the nuclear reactor of the future may not be limited to the central power station nor to naval vessel propulsion. Nuclear reactor designs for use in space travel will obviously change the emphasis on reactor weight and will also have great impact on the biological shielding and specific power of the reactor. If this application holds promise in the future, one can expect a great deal of analytical and experimental work in the field of the interaction of radiation and matter for shielding purposes.

Glossary

Control material = movable neutron absorbing material inserted in reactor core to compensate for changes in reactivity during operation.

Criticality = the state of a reactor in which the power or neutron flux is independent of time, without an external source of neutrons. Here reactivity equals zero, or multiplication constant equals unity. Term also used as colloquial equivalent of reactivity.

Cross section = a property of nuclei representing the probability that, under given conditions, certain reactions will take place. For neutron interactions, the cross sections may be for absorption, fission or scattering.

Moderator = a substance having a large scattering cross section and small absorption cross section for neutrons, included in a reactor to slow down neutrons to energies where fission readily occurs.

Poison = a material highly absorbent of neutrons. May be included for control purposes, or may be present in structure, moderator, and fission products.

Reactivity = a quantity determining the rate at which the power level of a reactor is changing with time. Equal to $(k_{eff}-1)/k_{eff}$, where k_{eff} is the effective multiplication constant of the core.

Reflector = a moderator which surrounds the core to reflect neutrons back which would have escaped. This process results in a core of given geometrical size being more reactive with a given fuel loading than the same reactor without a reflector.

Resonance absorption = absorption of neutrons in nuclei at certain energies, where the absorption cross section is very large (resonances).

Shutdown = term used to express the reactivity or the effective multiplication constant of a core when all control elements are fully inserted.

Xenon transient = the time variation in the effective cross section and core reactivity, following power operation and shutdown, due to the highly absorbing fission product xenon. The quantity of xenon in the core builds up during operation to a steady value proportional to neutron flux and after shutdown builds up from the radioactive decay of the fission product iodine while decaying radioactively itself. The amount of xenon thus reaches a maximum some time after shutdown and then decreases again.

IT IS WELL KNOWN that both the human and the dog's heart may be thrown into ventricular fibrillation by 60-cycle a-c shocks, resulting in the cessation of circulation followed by death. There are, however, little data available as to the magnitude of the current of various durations that will result in fibrillation, nor is there much information as to how the induction of fibrillation is influenced by the timing of the shock in the heart cycle. Ferris, Williams, Spence, and King[1] found that the sheep's heart was most vulnerable to shocks that fell during the *T* phase of the electrocardiogram of the heart.

The effect on the dog's heart of 60-cycle a-c shocks of 1/120, 1/60, 1/12, 1/6, 1/3, 1, 2, and 5-second durations was investigated for the current path from the right foreleg to the left hind leg. At each shock duration the minimum current needed to throw the ventricles into fibrillation, and the vulnerable period, if any, were determined. When fibrillation occurred it was arrested with the a-c closed-chest defibrillator, and normal sinus rhythm was restored.

Objectives

The objective of this study was twofold:

1. To investigate the effects of a-c shocks of varying durations, occurring at different places in the heart cycle, and to determine the magnitude of the minimum current and its position in the heart cycle that would result in fibrillating the heart.
2. To provide an opportunity for a thorough test of the a-c closed-chest defibrillator.[2,3]

The dog was used as the experimental animal in this investigation.

Heart Cycle

In order to identify the various phases of the heart cycle, a typical electrocardiogram (ECG) and its relationship to activity in the heart are shown in Fig. 1. A current flow throughout the heart is associated with its action, and this current flow produces a potential of a few millivolts at the extremities which is recorded as the ECG. The components of the ECG are the *P* wave, the QRS complex, and the *T* wave.

With the heart polarized, the action begins with the *P* wave, which originates in the sino-auricular (SA) node and which precedes the contraction of the auricles. The excitation initiated by the *P* wave travels to the auricular ventricular (AV) node and from there to the right and left ventricles, producing the *QRS* complex, which takes place just prior to the contraction of the ventricles. Following the contraction, the heart is in a depolarized state for a brief period. Then the *T* wave appears, which represents the repolarization phenomena. The repolarized heart rests for several milliseconds before the beginning of its next cycle.

Equipment

This investigation covering shocks of various durations and magnitudes required the utilization of special and diversified equipment, in the following four categories: 1. Recording equipment for measuring physiological and electrical variables. 2. Sources of adjustable voltages. 3. Provision for controlling the instant in time when the shock was initiated. 4. Means of controlling the length of the shock.

Recording Equipment

The recording equipment was a 4-channel Sandborn Poly Viso Recorder. This made it possible to record not only the ECG, but also the shocking current and the blood pressure simultaneously, and accurately to determine the instant in the heart cycle when the shock was applied.

1. *Physiological Variables*

Since the electric shocks were sent through the animals from the right foreleg to the left hind leg, the ECG potentials for recording the heart action at first were picked up by leads attached to the other

extremities. The high voltages used in applying the shock interfered with the ECG traces and made reliable records difficult to obtain. It was found that satisfactory records were regularly obtained from a small electrode on the chest over the heart and an electrode on the right hind leg.

The blood pressure was recorded on the second channel of the recorder by means of a Statham Strain Gauge Pressure Transducer connected to a cannula in either a femoral or carotid artery.

2. *Electrical Variables*

A small known noninductive resistance was inserted in series with the grounded end of the high-tension side of the shocking transformer. The voltage drop across this resistance produced by each shock was recorded on the third channel. Thus the instrument simultaneously recorded, not only the heart actions and the blood pressure, but also the magnitude, duration, and position in the heart cycle of the current. In a number of runs a potentiometer was connected across the shocking circuit and a small fraction of the high voltage was recorded on the fourth channel of the recorder. This served as a check on the duration and position of the shock.

For the 1/120- and 1/60-second shocks the response of the recorder was not sufficiently good to register these peak currents. Therefore, in order to obtain magnitude of these currents it became necessary to photograph their current traces on a calibrated oscilloscope. The recorder, however, served to indicate their position in the heart cycle.

VOLTAGE SUPPLY

In all of the experiments transformers were used to isolate the animal circuit from the primary a-c power supply. Two 5-kva transformers of different ratios were used, one connected either 1 to 2.5 or 1 to 5, and the other either 1 to 10 or 1 to 20. The fine control of the shocking potentials, essential to the determination of the minimum fibrillating current at a given shock duration, was provided by a 40-ampere continuous-duty Variac autotransformer inserted in the primary circuit of the transformer.

SHOCK POSITION CONTROL

In order to obtain a signal to position the shock at the desired point in the heart cycle, a square-wave generator with a variable-delay circuit was used. This generator was synchronized with the *R* wave of the ECG, and the position of its square-wave output with respect to the heart cycle could be set at any point. The synchronizing voltage conveniently enough came from an *R-C* circuit, which shaped the saw-toothed voltage of the horizontal deflection circuit of the scope to a sharp spike in phase with the start of the sweep and the upstroke of the *R* wave. Thus the output of the square-wave generator could be positioned at any desired point in the heart cycle.

The brief square-wave pulse was fed to the input of the unused channel of a dual-beam oscilloscope where its relative position in the heart cycle could be observed at all times. When it was desired to apply the shock to the animal a button was pressed which applied the generator pulse to a small fast-acting relay. This relay served to actuate the timer equipment which regulated the duration of the shock.

DURATION OF SHOCK

Two different methods were used to regulate the duration of the shocks. For shocks ranging from 1/120 (1/2 cycle of 60 cycles) second to 1/6 second (10 cycles), a special circuit gated the grid circuits of two back-to-back thyratrons in the primary circuit of the supply (the higher voltage, either supply) transformer. The gating circuit was adjusted to count

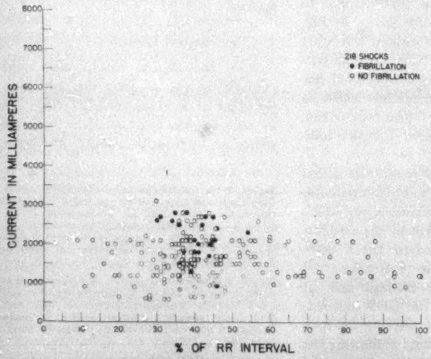

Fig. 2. 1/120-second a-c 60-cycle shock

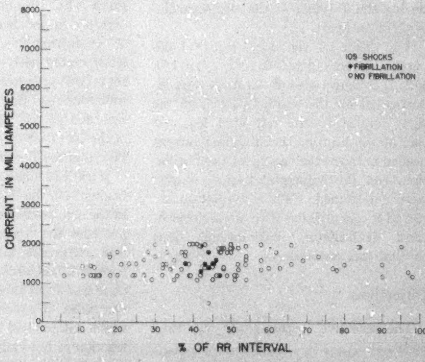

Fig. 3. 1/60-second a-c 60-cycle shock

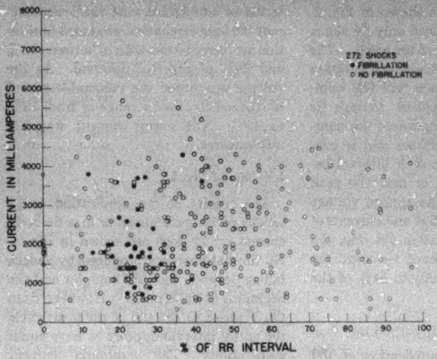

Fig. 4. 1/12-second a-c 60-cycle shock

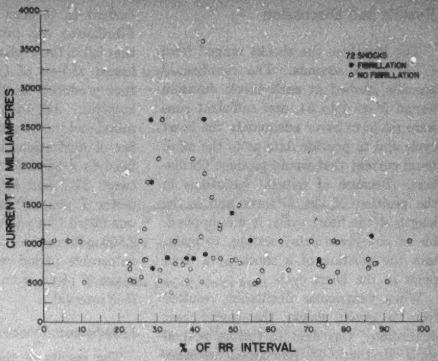

Fig. 5. 1/6-second a-c 60-cycle shock

off a certain number of cycles. It operated upon receipt of the starting signal from the quick-acting relay actuated by the square-wave generator. Thus the thyratrons acted as a precision controlled timer switch in the primary of the transformer, and the shock always started at the zero point of the a-c wave.

For shocks ranging from 1/3 to 5 seconds, the duration was regulated by an adjustable mechanical timer driven by a synchronous clock motor. The signal from the square-wave positioning generator closed a relay in the timer which applied the shock for the duration to which the timer had been set.

Procedure

The dogs, ranging in weight from 8 to 16 kilograms, were anesthetized with morphine and ether. A trachea tube was inserted and connected to a motor-driven respirator which ventilated the lungs with a mixture of air and ether. The hair was clipped from the chest and from the extremities. A cannula was inserted in an artery and connected to the blood-pressure gage transducer. Electrodes, each 1 inch by 2 inches, were strapped on the extremities. Electrode jelly was used to insure good electrical contact.

A normal record of the heart action and the blood pressure was taken on the recorder. Then the electrocardiograph leads were disconnected from the right foreleg and left hind leg, and connected either to the other extremities or to a chest electrode and the right hind leg. The high-tension leads from the transformer were then connected to the right foreleg and the left hind leg.

The electric circuits and controls were adjusted to provide a shock of the desired voltage, duration, and position in the heart cycle. The depth of anesthesia was carefully adjusted until the eye reflex was only just present. Then the recorder was started and the actuating button pressed sending the shock through the animal. From the record, the position of the shock, its duration, the magnitude of the current, and the effect on the heart and blood pressure were noted. If fibrillation occurred, the heart was defibrillated, using the closed-chest a-c defibrillator.

If the shock resulted in fibrillation, the shocking voltage was lowered by means of the Variac, and the run repeated after the heart had returned to normal sinus rhythm. If the shock did not fibrillate the heart, the voltage was raised before the next shock.

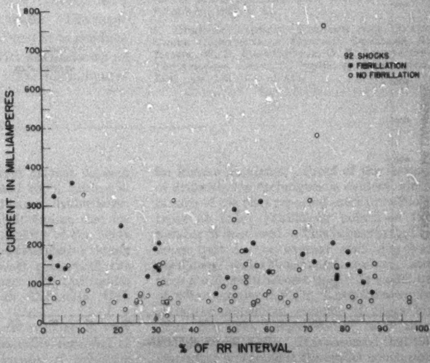

Fig. 7. One-second a-c 60-cycle shock

Results and Discussion

The length of the shocks ranged from 1/120 to 5 seconds. The number of animals studied at each shock duration varied from 4 to 34, and sufficient runs were made to cover adequately the heart cycle and to provide data as to the minimum current that would produce fibrillation. Because of natural variations in the position of the *T* wave and in the length of the heart cycle, it was impossible at any given delay setting, to maintain the position of a shock at a fixed point in the heart cycle.

When ventricular fibrillation resulted from a given shock, the closed-chest defibrillator was used to restore normal sinus rhythm. It functioned satisfactorily in every instance.

The results are plotted on eight charts, Figs. 2 through 9. The abscissa represents a complete heart cycle where the *R–R* interval is expressed as 100%. The ordinate is the current in milliamperes. The position of the beginning of each shock in the heart cycle, as well as the current, is shown by a small circle. If the shock produced ventricular fibrillation the circle appears as a black dot.

A normal dog's heart beats at a slightly faster rate than a human heart, but in these experiments the anesthetized animal's pulse ranged from 150 to 240 beats per minute, averaging about 200 beats per minute. Therefore, the average *R–R* interval is 0.3 second in these animals. In man the pulse varies from 70 to 90 beats per minute with an *R–R* interval of about 0.75 second.

1/120-Second Shock

The results of the application of 218 shocks of 1/2-cycle duration of a 60-cycle current on 14 dogs are shown in Fig. 2. Fibrillation was produced only by shock that fell in the *T* phase of the heart. The lowest current of 1/120-second duration that produced fibrillation was 925 milliamperes. As the applied voltage is raised and the current increased the number of fibrillations increases and is confined to a band in the *R–R* interval between 37% and 48%, or near the peak of the *T* phase. As the applied voltage was raised to a value that sent currents of 2,500 milliamperes through the dog, the vulnerable period widened to cover the entire *T* phase from 30% to 54% of the *R–R* interval.

1/60-Second Shock

The results of the application of 109 shocks of 1-cycle duration of a 60-cycle current on 7 dogs are shown in Fig. 3. Again the vulnerable period of the heart was found to be near the peak of the *T* phase, namely between the 38% and 47% limits of the *R–R* interval. The minimum current causing fibrillation was 1,200 milliamperes. In this test the voltage was not increased to high values as there were sufficient data to determine the minimum fibrillating shock and its location in the heart cycle.

1/12-Second Shock

The results of the application of 272 shocks of 5-cycle duration of a 60-cycle current on 34 dogs are shown in Fig. 4. Ventricular fibrillation was produced mainly by shocks falling earlier in the heart cycle than in the previous two short-shock durations. Here the vulnerable period ranged between 13% and 42% of the *R–R* interval. It should be kept in mind that a shock of this duration covers approximately 1/4 of the dog's *R–R* interval of 0.3 second. At the lower current the four shocks that produced fibrillation are confined to a span of between 22% and 28% of the *R–R* interval. As the voltage was raised the vulnerable period broadened to cover a range of from 13% to 42%. The lowest current was 720 milliamperes.

1/6-Second Shock

The results of the application of 72 shocks of 10-cycle duration of a 60-cycle current on 12 dogs are shown in Fig. 5. No fibrillations were produced by shocks falling between the *QRS* complex and the beginning of the *T* phase. However, from the *T* phase to the end of the heart cycle the entire interval appears to have equal vulnerability. The minimum current producing fibrillation was 690 milliamperes. The heart is vulnerable from the start of the *T* wave (28%) to near the end (87%) of the heart cycle.

1/3-Second Shock

The results of 122 shocks of 20-cycle duration of a 60-cycle current applied to 21 dogs are given in Fig. 6. The duration of these shocks covered the entire cycle of the dog's heart and the results show clearly that the vulnerable period extends over the entire heart cycle. The minimum current producing fibrillation was 347 milliamperes.

One-Second Shock

The results of 92 1-second shocks of 60-cycle current applied to 15 dogs are shown in Fig. 7. The results show clearly that the vulnerable period extends over the entire heart cycle when the duration of the shock covers more than one cycle. The minimum current required to induce fibrillation was 71 milliamperes.

Table I. Magnitude of Threshold Current

Shock Duration, Seconds	Threshold Current			
	Current, Milliamperes			
	Lowest	Second	Third	Average
1/120	925	1,175	1,300	1,130
1/60	1,200	1,200	1,299	1,230
1/12	720	750	880	780
1/6	690	750	800	770
1/3	347	375	412	380
1	71	73	80	75
2	77	91	120	96
5	42	56	58	52

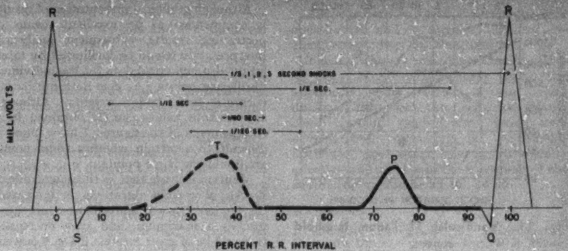

Fig. 10. Vulnerable period, dog's heart

Two-Second Shock

The results of 41 2-second 60-cycle shocks applied to 10 dogs are shown in Fig. 8. The results again illustrate the fact that the entire heart cycle is vulnerable when the shock duration covers several heart cycles. The minimum fibrillating current measured was 77 milliamperes.

Five-Second Shock

Only 18 5-second shocks were applied to a total of 4 animals. The results are shown in Fig. 9 and it is clear that the entire heart cycle is vulnerable. The lowest fibrillating current found was 42 milliamperes.

Threshold Current

We have arbitrarily selected, as a measure of the magnitude of the threshold current, the average of the three lowest currents causing ventricular fibrillation. These are given in Table I.

It is evident that as the duration of the shock increases the fibrillating current decreases. Contacts of several seconds duration with 50-volt a-c circuits may result in a fatal accident.

RESISTANCE

The resistance of the current pathway through the animals was measured in 40 tests, and ranged from 420 to 930 ohms, the average being 650 ohms. This checks with the value of 700 ohms found in previous tests[4] using this same current pathway.

VULNERABLE PERIOD

Fig. 10 presents the spans of the heart cycle covered by the beginnings of the applied shocks of different durations that produced fibrillations. These spans are superimposed on an ECG to show the vulnerable periods found. The *T* wave, which usually varies slightly in position and length, is shown as a broken line covering its normal range of variation.

As the duration of the shock decreases the vulnerable period of the heart cycle narrows and for very short shocks is located in the *T* phase.

Summary

This paper presents the results of an investigation of the production of ventricular fibrillation caused by shocks ranging in duration from 1/120 second to 5 seconds. A vulnerable period in the vicinity of the *T* phase of the heart cycle exists for short shocks. The entire heart cycle is vulnerable to shocks that are of sufficient duration to cover it, irrespective of when contact is first made. The magnitude of the minimum current to produce fibrillation of the ventricles was shown to decrease from about 1,200 milliamperes for 1/120-second shocks to near 50 milliamperes for 5-second shocks for a current pathway from right foreleg to left hind leg in an ether-anesthetized experimental animal. The resistance of this pathway averaged 650 ohms. When fibrillation occurred it was successfully arrested with the a-c closed-chest defibrillator.

Since it is known[5] that as the magnitude of shocks of certain durations is increased the tendency to cause fibrillation decreases, it would be of interest to extend this study to determine whether this holds true for shocks of all durations.

Discussion

Charles F. Dalziel (University of California, Berkeley, Calif.): Undoubtedly this paper is the most significant contribution to our knowledge on the effects of electric shock on the heart since publication of the AIEE paper by Ferris, King, Spence, and Williams 23 years ago (see reference 1 of the paper). The profession is greatly indebted to Dr. Kouwenhoven and his associates for successfully reaching their two most important objectives, namely the quantitative determination of the minimum current causing ventricular fibrillation and 100% success in using their a-c closed-chest defibrillator. Also of importance is their finding that for short shocks the susceptibility of the heart to fibrillate depends upon the relative timing of the shock to the heart cycle, and the generally good agreement with the results previously obtained at Columbia University.

The success of the defibrillator is very encouraging, as it is generally regarded as the most promising means of arresting ventricular fibrillation thus far developed for human accidents. Proof of the success of defibrillation techniques is evident, since in each of the tests reported there are almost twice as many fibrillating points as the number of dogs used. This is interpreted to mean that on the average each dog was fibrillated, defibrillated and revived, and then fibrillated a second time. It would be of great interest for Dr. Kouwenhoven to state the maximum number of times his prize dog was "electrocuted" and then brought back to life. It is assumed that the statement will confirm the earlier conclusion by Ferris and his associates that if the heart

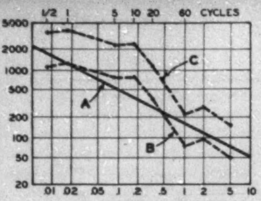

Fig. 11. Ventricular fibrillation threshold currents

A—Current that will not cause ventricular fibrillation in men determined by Dalziel in reference 1 of this discussion

B—Ventricular fibrillation threshold for dogs as determined in the paper

C—Threshold for dogs multiplied by 3 to approximate threshold for men

is not damaged and is given time to return to normal, successive shocks have no cumulative effect on the susceptibility of the heart to fibrillate.

The vulnerable period of the dog's heart illustrated in Fig. 10 is most interesting. It is entirely possible that the period when the heart is susceptible to fibrillate may span even shorter and shorter percentages of the *T* phase as the shock duration is further decreased. This may explain why accidental deaths due to impulse shocks, such as those associated with lightning generators and capacitors, are so infrequent.

The following ideas are suggested with the thought of improving the paper. The authors state that for shocks ranging from 1/120 to 1/6 second the shocks always started at the zero point of the a-c wave. This statement is interpreted to mean that the shock current was sinusoidal, and therefore the d-c component was zero. For shocks ranging from 1/3 to 5 seconds the duration was regulated by a mechanical timer and it is likely that the shocks occurred at random with reference to the shock-voltage wave. However, since the current was limited by variable-ratio transformers in series with the body resistance of the animal which averaged some 650 ohms, the *X-R* ratio was probably small and the resulting d-c component of shock current, even when present, would likely be of relatively short duration with respect to the duration of the shock. For these reasons it is likely that the fibrillating currents given in Table I and in Figs. 2–6 were nearly symmetrical rms milliamperes. In the interest of both clarity of presentation and possible subsequent application to accidents, it is suggested that the ordinates of Figs. 2 to 9 be labeled "Current in Symmetrical Rms Milliamperes."

It is requested that the average body weight of the animals fibrillated be inserted directly on Figs. 2 to 9 or given in tables, or in the text in paragraphs discussing the separate shock-duration tests. It would seem that the average weight should be computed from body weights for each fibrillating point, that is, animals fibrillated more than once should be considered the same as if they were new animals.

Although graphical presentation of results is commended as an excellent means of portraying results, subsequent analytical interpretation would be facilitated by tabulating also numerical data for the individual fibrillating points, i.e., give both fibrillating currents and body weights. Although approximate values can be obtained from enlargements of the figures, I have found it difficult to ascertain whether some points are double or triple points.

Mention is made that as the magnitude of shocks of certain durations is increased, the tendency to cause fibrillation increases, reaches a maximum, and then decreases. It would be of great interest if Dr. Kouwenhoven and his associates would find it possible to extend the study to determine whether this holds for shocks of all durations.

As an experimenter in this same general field, I feel very special recognition and sincere thanks are due these investigators and their sponsors for the great expenditure of time, thought, and resources, and the meticulous care required to observe, analyze, and record the 944 shock tests reported in this paper.

R. X. French (Sargent & Lundy, Chicago, Ill.): This paper is a valuable addition to the knowledge of the effect of electric shocks on heart action. Of major interest is the fact that the experimental results agree with the threshold fibrillation current of 100 milliamperes for shock duration in the order of 1 to 3 seconds determined by L. P. Ferris, et al, in 1936 (reference 1 of the paper). The most valuable contribution of this paper is the experimental verification of C. F. Dalziel's analytical derivation of the relationship between shock duration and fibrillation threshold current.[1]

The solid line on Fig. 11 shows Dalziel's threshold currents plotted against shock duration. It represents the current that $99^1/_2\%$ of all men could withstand without ventricular fibrillation. Curve *B* is plotted for the average of the three lowest currents that produced ventricular fibrillation in the dogs used in the experiments covered by the paper. Curve *C* is plotted for the dog threshold currents multiplied by 3 in order to approximate the threshold current for men. The multiplier is somewhat arbitrary. It was determined from the relative body weights of the dogs used in the experiments and data presented in reference 1 of the paper.

Comparison of the approximate threshold for men with Dalziel's curve (*A*) shows a reasonable safety factor and verifies that Dalziel's criterion for safe current should be used in the shock-time range of 0.01 second to 5 seconds. This criterion was used in the recent AIEE Committee Report on surface gradients.[2]

It would be interesting to have the authors discuss possible reasons for the dip in the threshold current at 1-second shock duration. Also, any comments that they may have on the apparent flattening of the curve at the low-shock duration end would be of interest since it is usually considered that the safe current increases with shorter shock durations, particularly for shocks of the impulse variety. Do the authors believe that the anesthetic affected the dog's response to shocks? Do the authors have any comments on converting animal data to data for men?

W. B. Kouwenhoven, G. G. Knickerbocker, R. W. Chesnut, W. R. Milnor, D. G. Sass: The authors are not able to name their "prize dog" as defined by Professor Dalziel. However, one animal after having been thrown into ventricular fibrillation nine times, and defibrillated each time, was retired to his cage for two months. At the end of this period he was sacrificed and subjected to autopsy. No evidence of trauma was found.

It is possible, as suggested by Professor Dalziel, that the period of the dog's heart when it is most susceptible to fibrillation, may span even shorter percentages as the shock duration is decreased. We made a total of 129 experiments on 21 mongrel dogs to determine vulnerability to single stimuli consisting of capacitor discharges through

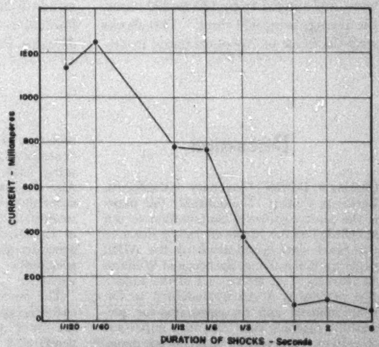

Fig. 12. Average of lowest three fibrillating currents versus shock duration

external electrodes on the thorax.[1] Capacitors of 25 to 50 microfarads charged to voltages of 1 to 4 kv were used. Voltages from 2 to 4 kv produced multiple ventricular extra systoles usually followed by a gradual return to normal rhythm. In 9 out of 35 experiments with peak voltages of 2.7 to 4 kv the ventricular extra systoles developed into an established ventricular fibrillation. Susceptibility to these effects extended throughout most of the heart cycle and was not limited to the relatively short late systolic period.

The shocking currents in our study were supplied by the local power system and may be considered as 60-cycle rms currents with a zero or negligible d-c component.

The weights of our animals were recorded but we failed to find any correlation between the body weights and the minimum fibrillating current. The objective of our study was to determine the effects of shocks applied at different points in the heart cycle, and no attempt was made to ascertain the minimum fibrillating current of each animal at each point in the heart cycle.

The discussion submitted by Mr. French sets forth certain conclusions to which the authors find it difficult to subscribe. When the minimum fibrillating currents are plotted, as shown in Fig. 12, it appears that there exist at least two, if not three, plateaus. It is our opinion that the effect on the heart of electric shocks of varying durations depends upon more than a single biological mechanism or reaction.

All dogs used in these experiments were anesthetized and we have no data for unanesthetized dogs for comparison.

The authors are not able either to affirm or deny Mr. French's query as to the application of these results to man. They do know that both the open- and closed-chest electrical defibrillators, which were developed for arresting the ventricular fibrillating dog's heart, have proved equally effective and reliable in the treatment of the fibrillating human heart.

Eddy-Current Losses in Solid and Laminated Iron

PAUL D. AGARWAL
ASSOCIATE MEMBER AIEE

Synopsis: In this paper formulas are developed, on the basis of simple physical conceptions, for the calculation of eddy currents in solid and laminated iron, which, as the experiments presented show, enable the losses caused by eddy currents to be predicted with surprising accuracy. A simple formula for the calculation of the power factor (pf) that the magnetic circuit reflects into the magnetizing winding is also presented.

Solution of Maxwell's equations, when a sinusoidal mmf (magnemotive force) is impressed on a core composed of steel plates, and under the conditions of an ideal rectangular B-H curve, Fig. 1, gives a wave of flux density B_0 that enters each plate from the outside surface at the start of each half-cycle, and penetrates to a depth δ, the "depth of penetration." If δ is less than d, the half thickness of the plate, the inner part of the plate remains unmagnetized, and the magnetic flux as well as the eddy currents are confined to a layer of depth δ on each surface of the plate. If δ is greater than d, the flux-density waves from the two sides meet in the center of the plate before the end of the half-cycle, and for the remainder of the half-cycle the plate remains magnetized to the value B_0. In this case, therefore, the eddy currents flow during the first portion of each half-cycle and are zero during the period the plate is fully magnetized. Waveshapes of voltages induced in search coils placed around the core substantiate this experimentally. The eddy-current loss and the pf of the magnetic circuit are calculated by the Poynting vector theorem.

Since the assumption of a rectangular B-H curve is not exact, it is necessary to choose a limiting value of the saturation flux density that will provide the best agreement between theory and test. After some study, the best value of B_0 to be used in the formulas has been determined empirically to be 3/4 B_m, where B_m is the flux density obtained from the static magnetization curve of the material corresponding to H_m, the peak of the impressed mmf. With this value of B_0, the formula gives the eddy-current losses with satisfactory accuracy over the entire range of tests performed.

Tests were made over a wide range of variables: plate thickness 0.025–1 inch; frequency from 15–2,000 cps (cycles per second); and applied mmf from 25–450 peak-ampere turns per inch. The calculated and measured values of eddy-current losses are within about 15% of each other over the entire range of the tests. In different samples of the same material, the value of H for the same B may vary within ±10–15%, and hence an error of this order is to be expected in estimating these losses.

WHEN IRON is subjected to an alternating mmf, energy is lost in the iron owing to the phenomena of eddy currents and hysteresis. In most applications the designer is interested in minimizing these losses to improve the efficiency The development of magnetic materials and techniques has kept pace with this requirement. However, many parts of machines cannot be adequately laminated, and solid surfaces are exposed to alternating fields; such as, end plates of rotors and stators in the field of the end turns, transformer tanks in the field of current leads, and numerous others. On the other hand, there are applications like magnetic clutches and eddy-current brakes, where one tries to maximize these losses.

Therefore, the problem of estimating losses in solid and in laminated iron has been of prime concern to the research scientist and the design engineer. Magnetic circuits of transformers and rotating machines are built up of thin laminations and this leads many to think that with a fixed applied mmf the losses will increase with the thickness of laminations and would become excessive if the limit is reached; i.e., if the laminated body is replaced by solid steel. Because the shielding effect of eddy currents may actually reduce the losses, this concept is wrong. For a given total flux, however, the losses will increase steadily with increasing lamination thickness.

In spite of the enormous amount of work done in this field in the past 50 years, no theoretically sound formula has been developed which would give the iron losses within engineering accuracy over a wide range of material thickness, applied mmf

---

Paper 59-12, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted September 16, 1958; made available for printing November 10, 1958.

PAUL D. AGARWAL is with the University of Massachusetts, Amherst, Mass., and Consultant to the General Electric Company. This material is part of the thesis submitted for the degree of Doctor of Electrical Engineering at the Polytechnic Institute of Brooklyn, Brooklyn, N. Y.

The author is greatly indebted to the General Electric Company for its support of this research, and to Philip L. Alger, Consulting Engineer of that company, for his inspiring guidance and assistance, without which this work would not have been possible. The author would also like to express his deep appreciation to Dr. Ernst Weber, President of the Polytechnic Institute of Brooklyn, and Chairman of his Guidance Committee, for his critical review, helpful suggestions, and kind interest.

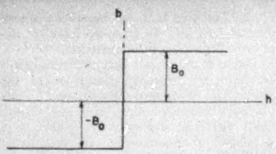

Fig. 1 (left). Assumed magnetization curve

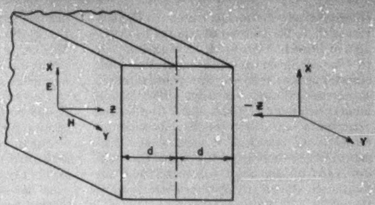

Fig. 2 (right). Plane waves penetrating inward from both faces of plate of thickness 2d

and frequency. The difficulty in deriving such a formula arises from the extremely nonlinear relation between B and H, which the hysteresis loop represents for a ferromagnetic material. Therefore, an exact mathematical calculation of the iron losses is not possible.

An approximate solution obtained by assuming the permeability to be a constant may yield good results so long as the material is being worked on the linear portion of the magnetization curve. However, it should be realized that even for weak magnetization a close examination of the magnetization curve will show that the assumption of linearity in actual practical cases is not justified. Also, at low densities hysteresis loss is predominant, and the division of the total measured losses into eddy-current losses and hysteresis losses depends on the assumptions made. The accuracy of these assumptions and, hence, the division of experimental losses is questionable. Since in most applications iron is saturated, the permeability will vary over a wide range $\mu_{\max}/\mu_{\min}=10\text{–}500$, more or less. Since the eddy-current losses as given by the linear theory are dependent upon the value of permeability, the results given by the linear theory will have little quantitative meaning except to give a physical conception of the phenomenon.

A careful review of the literature shows that many authors[1-3] have employed the rectangular B-H curve assumption in deriving their results, and MacLean[2] has obtained in this way formulas for the solid iron case. His analysis has been extended in this paper to the case of thin plates thus yielding the general formula. However, so far as the author is aware, no previous writer has derived the formulas for the laminated iron case that are developed here. Nor have any authors obtained satisfactory checks between calculated and test results over so wide a range of applied mmf, frequency, and plate thickness as are covered here.

Analysis

The assumed ideal magnetization curve under which the eddy-current phenomena are being analyzed is illustrated in Fig. 1.

Consider an iron plate of infinite dimensions in the xy plane, with its thickness $2d$ in the Z direction as shown in Fig. 2. Let a magnetizing winding, not shown in Fig. 2, produce and maintain on each face of the plate a uniform sinusoidal magnetizing force $H=H_m \sin \omega t$, in the Y direction with no variation in the X direction. The corresponding electric field will be normal to the magnetic field and, hence, in the X direction. Thus X-polarized plane waves impinge on the outside faces of the plate and propagate inward toward the center of the plate. Since this wave penetration is symmetrical with respect to the middle of the plate, the phenomena in the half thickness of the plate only needs to be considered. The waves enter the plate from the surface and penetrate inward with resulting attenuation. The movement of the front of the wave $h=0$ is of particular interest because, as a result of the assumed B-H curve, change in magnetization takes place only at this point. The wavefront $h=0$, with h increasing, is accompanied by a flux-density wave of constant amplitude $+B_0$. Thus, flux waves of density $+B_0$ penetrate from the faces into the plate. The extreme depth to which fields penetrate and beyond which there are no fields at all is called the "depth of penetration" δ. It should be noted that the term "depth of penetration" in the case of linear permeability has a different connotation.

Two cases now arise, one in which the depth of penetration δ is less than d, the half thickness of the plate, and the other in which δ is greater than d. In the first case, the fields penetrate to depth δ on each side of the plate and the inner part of the plate remains unmagnetized. In the second case, the two flux waves will meet at the center of the plate before the end of the half-period, and for the remaining part of the half-period there will be no change of flux in the plate. This induction remains in the form of remanent flux until it is annihilated by a negative field force.

At the end of the half-period, h at the surface becomes zero and is at the beginning of its negative half-wave. Now again a wavefront $h=0$, but with h decreasing, penetrates into the plate. This wavefront is accompanied by a flux-density wave of constant amplitude $-B_0$, and reverses the direction of magnetization in the plate. Thus, the plate is alternately magnetized to density $\pm B_0$ up to the depth δ or d whichever is smaller. The transition of magnetic induction takes place at a point $\zeta(t)$, which defines an xy plane, referred to here as the "separating surface." The separating surface moves parallel to itself with time.

Maxwell's Equations

Maxwell's field equations in media at rest and in integral form, neglecting displacement current, are

$$\oint \mathbf{h}\cdot d\mathbf{l} = \gamma \int_s \mathbf{e}\cdot d\mathbf{s} \tag{1A}$$

$$\oint \mathbf{e}\cdot d\mathbf{l} = \frac{\partial}{\partial t}\int_s \mathbf{b}\cdot d\mathbf{s} \tag{1B}$$

where γ is the conductivity and all variables are expressed in meter-kilogram-second units.

In the problem under consideration, the electric field has only an x-component e, and the magnetizing force and magnetic field only y-components h and b

$\mathbf{e}=\mathbf{i}e$

$\mathbf{h}=\mathbf{j}h$

This reduces Maxwell's equations to the following

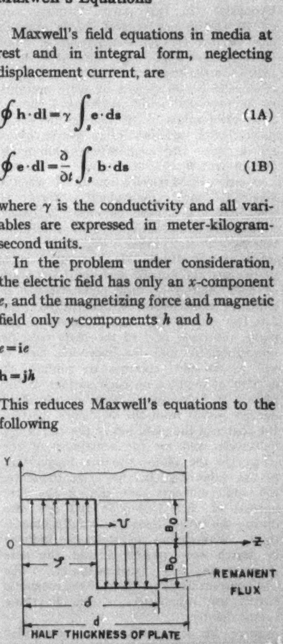

Fig. 3. Separating surface penetrating the plate

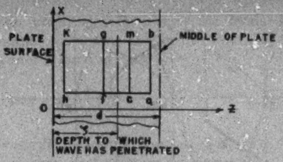

Fig. 4. XZ section of the plate

ab=cd=fg=hk
=unit length=1 meter

$$\oint h\mathbf{j}\cdot d\mathbf{l}=\gamma\int_s \mathbf{e}\cdot d\mathbf{s} \tag{2A}$$

$$\oint e\mathbf{i}\cdot d\mathbf{l}=-\frac{\partial}{\partial t}\int_s \mathbf{b}\cdot d\mathbf{s}=-\frac{\partial}{\partial t}(\phi) \tag{2B}$$

where ϕ is the flux passing through the surface around which the line integral is taken.

Let E, B, and H be the values of the variables at the surface, i.e., at $Z=0$. The solution of equations 2(A) and (B) is sought compatible with Fig. 1, the assumed magnetization curve, and with an impressed sinusoidal magnetizing force at the surface.

$$H=H_m \sin \omega t \tag{3}$$

The rectangular magnetization curve can be expressed as

$$B=B_0 \operatorname{sig} H \tag{4}$$

where sig H=sign of H and is the unit square wave associated with the sinusoidal H.

Consider a YZ section of half the plate as shown in Fig. 3. Let at any instant the separating surface be at a depth ζ and moving toward the center of the plate with a velocity v. Then in a time dt the flux $B_0\, v\, dt$ is built up and at the same time an equal amount of remanent flux is destroyed. Therefore, the rate of change of flux per unit length in the x direction is given by

$$\frac{d\phi}{dt}=2B_0 v \tag{5}$$

The line integral in equation 2(B) is easily evaluated in this case by taking the surface s in the xz plane; see Fig. 4.

Consider the closed loop $abmc$ in Fig. 4. There is no change of flux taking place in this area, which shows that there is no electric field beyond the separating surface.

Now consider the closed loop $cmgf$, which encloses the separating surface. From equations 2(B) and 5

$$e_{cm}+e_{gf}=2B_0 v$$
$$=2B_0\frac{d\zeta}{dt} \tag{6}$$

$$\text{or}\quad e_{gf}=2B_0\frac{d\zeta}{dt}\ \text{since}\ e_{cm}=0 \tag{7}$$

There is no change of flux to the left of the separating surface and, hence, considering loop $fgkh$ will show that

$$e_{fg}=e_{hk}=E \tag{8}$$

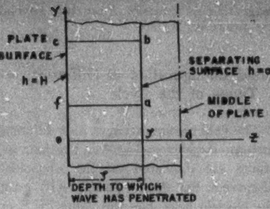

Fig. 5. YZ section of the plate

ab=cf=unit length
=1 meter

This shows that the electric field in the region to the left of the separating surface, that is, $0<Z<\delta$, is the same everywhere, and its magnitude is equal to E the value of the electric field at the outside surface, and the discontinuity in the electric field occurs at the separating surface.

To evaluate the line integral in equation 2(A), consider the loop $abcf$ in Fig. 5 with surface in the yz plane. The magnetic field intensity h is zero at the separating surface and has no component in the z direction.

$$\therefore \oint_{abcf}\mathbf{h}\cdot d\mathbf{l}=H$$
$$=\text{current enclosed in loop } abcf$$
$$=\gamma E\zeta \tag{9}$$

giving

$$\frac{\partial h}{\partial z}=\frac{H}{\zeta}=\gamma E \tag{10}$$

From the foregoing equation the following conclusions are drawn:

1. The induced eddy currents flow with uniform density in the region between the outside surface of the plate and the separating surface, and are zero beyond.
2. The magnetic field intensity h decreases linearly from its value H at the outside surface ($z=0$), to zero at the separating surface ($z=\zeta$).
3. The electric-field intensity e, and

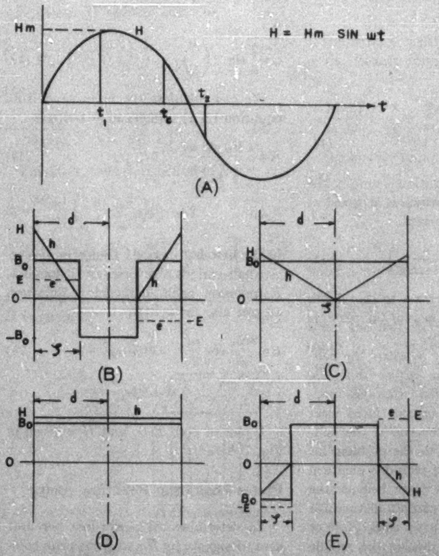

Fig. 6. Field configurations at four different instants

A—Mmf wave

C—Flux waves have just reached the center of the plate. $\zeta=d$, $e=0$, $t=t_0(-)$
D—After the flux wave has reached the center of the plate, h becomes uniform. $h=H$, $e=0$, $t=t_0(+)$
E—New magnetic flux wave has penetrated for a distance ζ $t=t_2$
t_0=the instant at which separating surfaces reach the middle of the plate

magnetic-field intensity h are zero beyond the separating surface.

Field Configuration at Different Times of the Cycle

The field configuration at four different instants is given in Fig. 6. The four instants are indicated on the sinusoidal H curve in Fig. 6(A). In Fig. 6(B), $\zeta<d$, the electric field, has the value $e=E$ or zero as shown, and h is linear to ζ and then zero as shown. When the separating surface moving inward reaches the center of the plate at $\zeta=d$ (say at $t=t_c$), the whole material is magnetized to saturation and no change of flux takes place for the remaining part of the half-cycle, i.e., during the interval between t_c and π/ω. After half a cycle, at $t=\pi/\omega$, the separating surface again starts from each face and reverses the direction of magnetization. During the interval t_c to π/ω, there is no change of flux in the plate and, hence, $e=0$. Substituting from Fig. 6(B) in equation 9

$$\frac{\partial h}{\partial s}=\frac{H}{\zeta}=\gamma E \qquad \zeta<d \text{ or } 0<t<t_c$$

$$=0 \qquad t_c<t<\frac{\pi}{\omega} \qquad (11)$$

This means that after t_c, h everywhere jumps to the value H at the surface, thus becoming uniform. This is shown in Fig. 6(C). After half a cycle, at $t=\pi/\omega$, the magnetic-field intensity at the surface H is equal to zero. Therefore, h is zero everywhere in the material, and a new separating surface of oppposite magnetic induction starts from the two ends. This condition is shown in Fig. 6(E).

Thus Maxwell's equations have been replaced by the following pair

$$\left.\begin{aligned}\frac{H}{\zeta}&=\gamma E\\ E&=2B_0\frac{d\zeta}{dt}\end{aligned}\right\} \qquad \begin{aligned}&0<t<t_c && (12A)\\ &\zeta<d && (12B)\end{aligned}$$

or

$$\left.\begin{aligned}h&=H\\ e&=0\end{aligned}\right\} \qquad t_c<t<\frac{\pi}{\omega}$$

Eliminating E between equations 12(A) and (B)

$$2\zeta\frac{d\zeta}{dt}=\frac{H}{\gamma B}=\frac{H_m \sin \omega t}{\gamma B_0 \operatorname{sig} H}$$

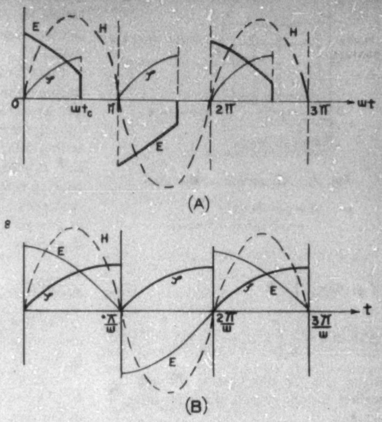
$$\frac{d}{dt}(\zeta^2)=\frac{H_m}{\gamma B_0}\left|\sin \omega t\right| \qquad 0<t<t_c \qquad (13)$$

Equation 13 shows that the transition point always moves from the outside surfaces toward the center of the plate where it ceases to exist, and repeats every half-cycle when H becomes zero at the surface.

Fig. 7. Plots of waveshape

A—H, E, and ζ

B—H, E, and ζ for the solid-iron case



Depth of Penetration

If the plate is thick enough, then the transition point ζ will penetrate to its maximum depth, depth of penetration, δ at the end of the half-cycle. The motion of the separating surface as a function of time, in the first half-period, can be evaluated as follows:

$$\frac{d\zeta^2}{dt}=\frac{H_m}{\gamma B_0}\sin \omega t \qquad \omega t<\pi$$

$$\therefore \zeta^2=\int_0^t \frac{H_m}{\gamma B_0}\sin \omega t\, dt$$

giving

$$\zeta=\left(\frac{2H_m}{\omega\gamma B_0}\right)^{1/2}\sin\frac{\omega t}{2} \quad 0<t<\frac{\pi}{\omega} \qquad (14)$$

The depth of penetration is simply the maximum value of ζ which is attained at the end of each half-period.

$$\therefore \delta=\left(\frac{2H_m}{\omega\gamma B_0}\right)^{1/2}=\left(\frac{2}{\gamma\omega B_0/H_m}\right)^{1/2} \qquad (15)$$

The fields will penetrate to this depth when d, the half-thickness of the plate, is greater than or equal to δ.

In a thin plate, that is, where the half-thickness of the plate is less than the depth of penetration, the two waves moving inward from the outside faces meet at the center before the end of the half-period. The solution of the problem for this portion of the half-period is identical with that for the thick plate, because the electromagnetic wave can not distinguish whether it is penetrating a thick plate or a thin plate, until it reaches the middle and confronts the wave approaching from the opposite side.

Therefore

$$\zeta=\left(\frac{2H_m}{\gamma\omega B_0}\right)^{1/2}\sin\frac{\omega t}{2} \qquad 0<t<t_c$$

$$=\delta \sin\frac{\omega t}{2} \qquad (16)$$

where t_c is the time when the separating surface reaches the middle of the plate.

$$d=\delta \sin\frac{\omega t_c}{2} \qquad (17)$$

or

$$t_c=\frac{2}{\omega}\sin^{-1}\left(\frac{d}{\delta}\right) \qquad (18)$$

We can calculate the value of E from equation 12(A), which can be written

$$E=\frac{1}{\gamma}\frac{H_m \sin \omega t}{\delta \sin\frac{\omega t}{2}} \qquad 0<t<t_c \qquad (19)$$

$$=0 \qquad t_c<t<\frac{\pi}{\omega}$$

in the first half-period. Since in successive half-periods H reverses and ζ does not, E reverses each half-cycle. Equation 19 can also be written

$$E=\frac{2H_m}{\gamma\delta}\cos\frac{\omega t}{2} \qquad 0<t<t_c \qquad (20)$$

$$=0 \qquad t_c<t<\frac{\pi}{\omega}$$

A plot of $\zeta(t)$, $E(t)$, and H is given in Fig. 7(A).

Power Loss from Poynting Vector

To determine the power-loss per unit area, designate by $\bar{H}$ and $\bar{E}$ the peak complex amplitudes of H and the fundamental component of E. The Poynting vector $\bar{N}$ into the metal is

$$\bar{N}=N+jM=\frac{1}{2}E\bar{H}^{*} \tag{21}$$

where H^{*} means the conjugate of H. The real part N of $\bar{N}$ gives the power flow. Since H is sinusoidal, the harmonics of E do not contribute to the power flow; see Appendix I.

A complex surface impedance for the plane wave (wave impedance at the surface) $\bar{\eta}$ is usually designated by

$$\bar{\eta}=r+jx=\frac{\bar{E}}{H} \tag{22}$$

which gives

$$N=Re\bar{N}=\frac{1}{2}rH_m{}^{2} \tag{23}$$

The Fourier coefficients for the fundamental of E are obtained using Fig. 6 and equation 20,

$$A_1=\frac{2H_m}{\gamma\delta}\frac{\omega}{2\pi}2\int_0^{t_c}\cos\frac{\omega t}{2}\cos\omega t\,dt$$

$$=\frac{2H_m}{\gamma\delta\pi}\left(\frac{1}{3}\sin\frac{3\omega t_c}{2}+\sin\frac{\omega t_c}{2}\right) \tag{24}$$

$$B_1=\frac{2H_m\omega}{\gamma\delta\pi}\int_0^{t_c}\cos\frac{\omega t}{2}\sin\omega t\,dt$$

$$=\frac{2H_m}{\gamma\delta\pi}\left[\frac{4}{3}-\frac{1}{3}\cos\frac{3\omega t_c}{2}-\cos\frac{\omega t_c}{2}\right] \tag{25}$$

Equation 17 reduces these to

$$A_1=\frac{4H_md}{\delta^2\gamma\pi}\left[1-\frac{2}{3}\left(\frac{d}{\delta}\right)^2\right] \tag{26}$$

and

$$B_1=\frac{8H_m}{3\gamma\pi\delta}\left[1-\left(1-\frac{d^2}{\delta^2}\right)^{3/2}\right] \tag{27}$$

Therefore, the fundamental of E is

$$E_1=\frac{8H_m}{3\gamma\pi\delta}\left[\left(3\frac{d}{\delta}-2\frac{d^2}{\delta^2}\right)\cos\omega t+2\left\{1-\left(1-\frac{d^2}{\delta^2}\right)^{3/2}\right\}\sin\omega t\right] \tag{28}$$

and the peak complex amplitude of E and H is given by .

$$\bar{E}=\frac{8H_m}{3\gamma\delta\pi}\left[\left(3\frac{d}{\delta}-2\frac{d^2}{\delta^2}\right)-j2\left\{1-\left(1-\frac{d^2}{\delta^2}\right)^{3/2}\right\}\right] \tag{29}$$

$$\bar{H}=-jH_m \tag{30}$$

Substituting these in equation 22, the surface impedance is

$$\bar{\eta}=r+jx=\frac{\bar{E}}{\bar{H}}=\frac{16}{3\pi\gamma\delta}\left[\left\{1-\left(1-\frac{d^2}{\delta^2}\right)^{3/2}\right\}+\frac{j}{2}\left(3\frac{d}{\delta}-2\frac{d^2}{\delta^2}\right)\right] \tag{31}$$

The phase angle θ of the complex surface impedance $\bar{\eta}$ is equal to

$$\theta=\tan^{-1}\frac{x}{r}$$

Therefore from equation 31

$$\tan\theta=\frac{3\frac{d}{\delta}-2\left(\frac{d}{\delta}\right)^2}{2\left[1-\left(1-\frac{d^2}{\delta^2}\right)^{3/2}\right]} \tag{32}$$

Eddy-Current Loss and Pf Formulas

Therefore the pf that the eddy-current losses reflect into the exciting winding is

$$\text{pf}=\cos\theta=\cos\tan^{-1}\frac{3\frac{d}{\delta}-2\frac{d^2}{\delta^2}}{\left[1-\left(1-\frac{d^2}{\delta^2}\right)^{3/2}\right]} \tag{33}$$

The surface resistance is the real part of the surface impedance, and is given by

$$r=\frac{16}{3\pi}\frac{1}{\gamma\delta}\left[1-\left(1-\frac{d^2}{\delta^2}\right)^{3/2}\right] \tag{34}$$

The loss per unit area N, given by equation 23 is thus

$$N=\frac{8}{3\pi}\frac{H_m{}^2}{\gamma\delta}\left[1-\left(1-\frac{d^2}{\delta^2}\right)^{3/2}\right] \tag{35}$$

Solid Iron Case

By solid iron it is meant here the case when the half thickness of the plate is equal to or greater than the depth of penetration. The moving surface as a function of time is given by equation 14

$$\zeta=\left(\frac{2H_m}{\omega\gamma B_0}\right)^{1/2}\sin\frac{\omega t}{2}\qquad 0<t<\frac{\pi}{\omega}$$

$$=\delta\sin\frac{\omega t}{2} \tag{36}$$

The electric field at the surface can be obtained from equation 20, realizing that now the fields penetrate up to the end of the half-period.

$$E=\frac{2H_m}{\gamma\delta}\cos\frac{\omega t}{2}\qquad 0<t<\frac{\pi}{\omega} \tag{37}$$

A plot of $\zeta(t)$, $E(t)$, and $H(t)$ is given in Fig. 7(B). Again the fundamental of E is obtained by Fourier series, whereby

$$E_1=\frac{8H_m}{3\pi\delta\gamma}(\cos\omega t+2\sin\omega t) \tag{38}$$

and the peak amplitude of E and H is given by

$$\bar{E}=\frac{8H_m}{3\pi\delta\gamma}(1-2j) \tag{39}$$

and

$$\bar{H}=-jH_m \tag{40}$$

This gives

$$N=\frac{8}{3\pi}\frac{H_m{}^2}{\gamma\delta} \tag{41}$$

and

$$\text{pf}=\cos\tan^{-1}\frac{1}{2}=0.894 \tag{42}$$

It can be seen from equations 41 and 42 that the power-loss per square meter, and pf for the solid case, can be readily obtained from equations 33 and 35 by substituting $d/\delta=1$. The loss per square meter is independent of the value of d, so long as d is greater than δ. Therefore, the maximum value of d/δ to be used in equations 33 and 35 is unity.

Search Coil Voltage

The variation of flux in the 1-inch iron-ring specimens (Fig. 8) on the basis of the theory presented here can be calculated as follows

Let n = number of laminations in the ring $=\frac{1}{2d}$

Considering the general case when $d<\delta$, let the separating surface be at a depth ζ from the outside surfaces of the laminations.

ϕ = the instantaneous value of flux in the iron ring

$$\phi=2nlB_0\left(d-2\delta\sin\frac{\omega t}{2}\right)\qquad 0<t<t_c \tag{43}$$

and

$$=2nlB_0d\qquad t_c<t<\frac{\pi}{\omega} \tag{44}$$

The voltage induced in a search coil of N turns wound around the iron ring is given by

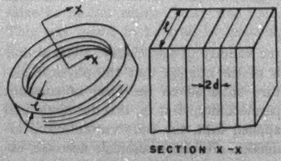


Fig. 8. Test specimen

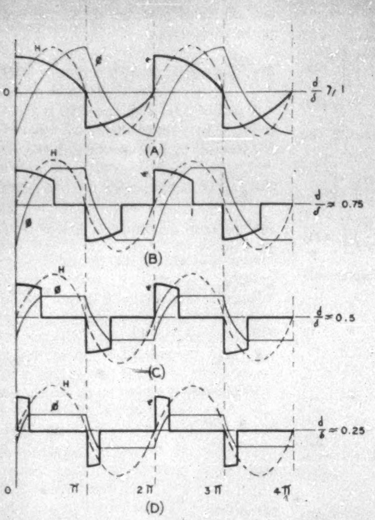

Fig. 9. Theoretical waveshape of e, ϕ, and H for various values of d/δ

$$e = -N\frac{d\phi}{dt}$$

$$= -2NnlB_v\delta\omega \cos\frac{\omega t}{2} \qquad 0<t<t_c$$

$$\text{or } \zeta<d$$

$$= 0 \qquad t_c<t<\pi/\omega \qquad (45)$$

The waveshapes of search coil voltage and induced flux therefore depend on the value of t_e and, hence, on the value of d/δ only. These waveshapes derived theoretically are shown in Fig. 9 for various values of d/δ.

The fraction of the half-period during which eddy currents flow is found to be:

$$= \frac{t_c}{T/2} = \frac{\frac{2}{\omega}\sin^{-1}\frac{d}{\delta}}{\pi/\omega} = \frac{2}{\pi}\sin^{-1}\left(\frac{d}{\delta}\right) \qquad (46)$$

This theory shows that in thin plates eddy currents do not flow continuously, but only for a fraction of the time during each half-cycle depending on the value of the fraction d/δ. This is contrary to the concept usually held, but an examination of the search coil voltages obtained in the tests will show that this is correct. The best proof of this theory lies in comparing the waveshapes of search coil voltages derived theoretically with those obtained experimentally.

Comparison of Theoretical and Experimental Waveshapes

Only a few of the more than 100 pictures taken experimentally are presented in Fig. 10, for comparison with those derived theoretically. Since the theoretical solution is based on an impressed mmf that is sinusoidal, every attempt was made to obtain sinusoidal mmf during the tests. To achieve this many practical problems were confronted, and that is why the experimental work was repeated three times before satisfactory conditions were obtained. In comparing the theoretical and experimental waveforms, it should be kept in mind that the actual magnetization curve is not exactly rectangular, and therefore no sharp corners should be expected in the experimental waveform of the search coil voltage.

An examination of Fig. 10 shows that the applied mmf was maintained essentially sinusoidal and that the theoretical and experimental waveshapes of search coil voltage correlate very well. Fig. 10(D) was purposely selected to show the maximum distortion that was tolerated in the applied mmf. Analysis showed that its third- and fifth-harmonic components were only 17.6% and 3%, respectively.

In Figs. 11(A) and 11(G), even though the peak applied mmf lies on the so-called linear portion of the magnetization curve, the waveform of search coil voltage is as predicted by the new theory, and not sinusoidal as given by the linear theory. The close correlation between the waveform of search coil voltages obtained experimentally and those predicted by this theory substantiates the validity of this theory. The author is of the opinion that the physical picture obtained on the basis of constant permeability, that is, that for sinusoidal applied field, the eddy currents and induction are also sinusoidal, decrease exponentially from the surface inward, and that eddy currents flow continuously, is

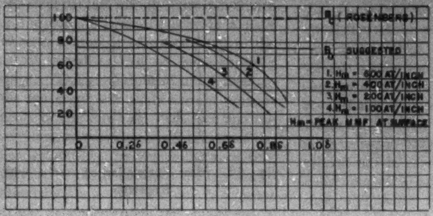

Fig. 11. Peak flux density at layers inside the material as a percentage of maximum density B_m at surface

far from correct and probably more misleading than helpful toward the actual solution of the problem.

Saturation Flux Density B_0

The value of B_0, the saturation flux density, to be used in any particular case is open to question. An assumption originated by Rosenberg[4] proposes that the value of B_0 should be that taken from the d-c magnetization curve of the material, corresponding to the peak field intensity H_m at the surface. Rosenberg made this assumption in order to make a simple calculation of eddy-current phenomena possible.

A careful examination of the problem will show why this assumption is not correct. If it is assumed that under dynamic conditions the induction density at any instant corresponds to the value of the magnetic-field intensity, given by the static magnetization curve of the material, then the value of B_0 will correspond to H_m at the outside surface layer only. Each succeeding inner layer is magnetized by a progressively smaller number of exciting ampere turns, because of the shielding effect of the eddy currents in the region between the outside surface and the layer under consideration.

Fig. 11 gives the peak flux density at various depths of the material and has been derived using Rosenberg's[4] eddy-current density curve and neglecting phase shift as suggested by him. Since, according to all eddy-current theories, the principal eddy-current losses occur in layers nearest the surface, where the phase shift is negligible, the shape of Fig. 11 would be essentially the same no matter which theory was used. This was found to be true by plotting Fig. 11 using other theories.

Fig. 11 shows that even for the case of strong magnetization (curve 1, for 600 ampere turns per inch) at depths 1/2 δ and 3/4 δ from the surface, the peak density reduces to about 80% and 60%, respectively, of the peak flux density at the surface. In the case of weaker magnetization, this reduction is even greater. An examination of Fig. 11 shows that some value of B_0 lower than B_m, the peak flux density at the surface, is more appropriate. It is recognized that an exact solution of the eddy-current phenomena is not possible, and that empirical calibration factors have to be determined to account for the departure from the ideal case assumed for analytical solution. It was found that the best value of B_0 to be used should equal 3/4 B_m, where B_m is the flux density corresponding to H_m, the peak value of mmf impressed at the surface, obtained from the d-c magnetization curve of the material. With the value of B_0, as Table I shows, the measured and calculated losses correlate very well over the entire range of tests performed. This value of B_0 is shown in Fig. 11 and clearly is more justified than B_m. The exact value of the fraction 3/4 can be open to question. The author believes that, since the shapes of B-H curves of most commonly used ferromagnetic materials do not differ materially, the fraction 3/4 will apply in almost all cases. The exact value of B_0 is, however, not too critical because the losses in solid iron are a function of $\sqrt{B_0}$.

For solid iron the power loss per square meter, assuming constant permeability, as derived by Ramo and Whinnery,[3] equation 1, page 241, is

$$N_1=\frac{1}{2}R_s|J_s|^2=\frac{1}{2}\left(\frac{\pi f\mu}{\gamma}\right)^{1/2}H_m^2$$

$$=\frac{1}{2}\left(\frac{\omega B_m/H_m}{2\gamma}\right)^{1/2}H_m^2 \text{ since } \mu=\frac{B_m}{H_m} \quad (47)$$

For a rectangular magnetization curve, the power loss, using $B_0=B_m$ as saturation flux density, is given by equation 41.

$$N=\frac{8}{3\pi}\left(\frac{\omega B_m/H_m}{2\gamma}\right)^{1/2}H_m^2=\frac{16}{3\pi}N_1=1.697N_1 \quad (48)$$

For a rectangular magnetization curve but using $B_0=3/4B_m$ as the value of saturation flux density, the power input formula becomes

$$N=\frac{8}{3\pi}\sqrt{\frac{3}{4}}\left(\frac{\omega B_m/H_m}{2\gamma}\right)^{1/2}H_m^2=1.47N_1 \quad (49)$$

Since the true magnetization curve of iron lies between the linear and rectangu-

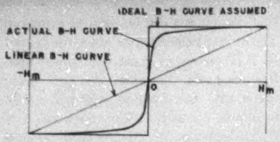

Fig. 12. True magnetization curve in relation to ideal and linear magnetization curves

lar case, as shown in Fig. 12, the rigorous solutions for the linear case as well as the rectangular case establish the limits within which the actual iron performs.

It is interesting to compare these results with that obtained by Rosenberg.[4] His formula is given in mixed units. When it is expressed in the units and notation of this paper, the following is obtained

$$N_{\text{Rosenberg}}=\left(\frac{4}{3}\right)\left(\frac{1}{2}\right)\left(\frac{\omega B_m/H_m}{2\gamma}\right)^{1/2}H_m^2$$
$$=1.333N_1 \quad (50)$$

Thus, Rosenberg's formula closely approaches equation 49 derived in this paper. This accounts for the fact that his formula has given good results, although it was based on intuition and not theoretically sound. His method does not give any information regarding the emf induced by the partial flux linkages, which are responsible for the reactance of the solid iron as seen from the exciting winding. The formulas derived in this paper are based on fundamental Maxwell's equations, and correctly explain all the phenomena associated with eddy currents. They have the further advantage of applying regardless of the thickness of the material.

Hysteresis

Hysteresis loss in solid iron has been a subject of much controversy. Some authors believe that in solid ferromagnetic materials the hysteresis loss is negligible compared with the eddy-current loss, and quite the contrary views are held by others.

When considering hysteresis, the ideal magnetization curve is that of a single crystal, shown in Fig. 13. The coercive force is shown as h_k. When hysteresis is neglected, the flux waves of saturation density B_0 penetrate the material from the surface when the field mmf H passes through zero. With hysteresis, the field mmf has to reach the value h_k, the coercive force, before the flux waves penetrate the material. The magnetic field h inside the material does not decrease from the value H at the surface to zero at the separating surface, see Fig. 13, but decreases to h_k. This results in an electric field and, hence, residual eddy currents of constant density in the region between the separating surface and d or δ, whichever is smaller. It has been shown by Haberland[1] that under these conditions the depth of penetration of flux is smaller because of the smaller effective field force, than in the case when hysteresis is neglected. Also, the peak value of the induced emf is smaller. According to Haberland,[1] the power loss due to eddy currents now becomes N_h = eddy-current loss per square meter taking hysteresis into account

$$=N\left(1-\frac{h_k}{4H_m}\right)$$

where N is power loss neglecting hysteresis.

The formula shows that, except for very low values of induction, the reduction in the eddy-current losses caused by hysteresis is small. This reduction is offset in some degree by the hysteresis loss.

The view that in massive iron hysteresis loss is negligible compared to eddy-current loss seems reasonable, because, except for very low values of induction, change of current amplitude is large for a small change of flux density amplitude, and eddy-current loss is a function of the former, and hysteresis loss of the latter.

Hysteresis loss was calculated for all the test points and found to be less than 4–5% except in the 1/16-inch laminations at low values of frequency and mmf. In view of the fact that an error of 10–15% is satisfactory in the estimation of iron losses, the effect of hysteresis in solid iron and thick laminations can be neglected. That is why in this paper test values are compared with calculated values which neglect hysteresis.

Effect of Temperature

The eddy-current loss formula, equation 35, for solid iron, that is, when $d/\delta \geqslant 1$ reduces to

$$N=\frac{8}{3\pi}H_m^{3/2}\left(\frac{\omega B_0}{2}\right)^{1/2}\sqrt{\rho} \qquad (51)$$

showing that in solid iron the eddy-current losses are proportional to the square root of the resistivity.

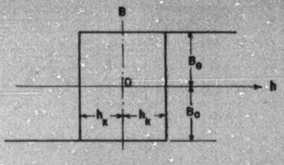

Fig. 13. Ideal magnetization curve with hysteresis

For very thin plates, that is, when $d/\delta << 1$, fourth and higher powers of d/δ can be neglected, giving

$$N\approx\frac{\sqrt{2}}{\pi}H_m^{1/2}(B_0\omega)^{3/2}d^2\frac{1}{\sqrt{\rho}} \qquad (52)$$

showing that for thin laminations the eddy-current losses are inversely proportional to the square root of the resistivity.

A series of tests were made on the ring specimens, which confirmed the temperature dependence of eddy-current losses as given above.

PF of the Iron Circuit

Although field theory is the foundation of all electromagnetic phenomena, it is very cumbersome in solving actual electromagnetic problems, except in the cases of simplest geometry. Most problems are conveniently solved by circuit theory and therefore, the proper values of resistance and reactance parameters are required to be used in the equivalent circuit, to take into account the effect of alternating field in iron. The proper value of R can be determined from the losses as calculated earlier, and an approximate value of power factor, and hence X, can be computed as shown in the following. Due to the nonlinearity of the magnetization curve of iron, both the voltage and the magnetizing current can not be simultaneously sinusoidal, and therefore it should be realized that in this case pf does not have its usual meaning.

Fig. 14 gives the approximate equivalent circuit and phasor diagram of the ring specimens on which iron loss tests were performed. The R_{h+e} branch is a resistive branch which is theoretically con-

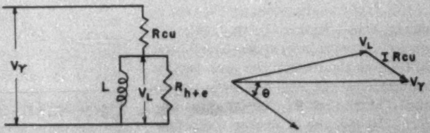

Fig. 14. Equivalent circuit and phasor diagram

nected in parallel with the pure inductance of the coil, in order to provide a path wherein a number of watts equal to the actual core loss can be hypothetically spent. The subscripts *h* and *e* refer to the hysteresis and eddy-current components of the core loss. The fact that the core loss in question is a function of the flux established by the inductance coil, together with the fact that the flux established by the inductance coil is to some extent dependent upon the magnitude of voltage drop across the ohmic resistance, dictates the circuit position of the hypothetical R_{h+e} branch.

$$V_L=\sqrt{(V_r-IR_{cu}\cos\theta)^2+(IR_{cu}\sin\theta)^2} \tag{53}$$

$$P_{\text{iron}}=W-P_{cu}$$

$$\text{Pf of the iron circuit}=\frac{P_{\text{iron}}}{V_L I}$$

The measured values of the power factor were determined by the foregoing equation. The analytical value of the pf is given by

$$\text{pf}=\cos\tan^{-1}\frac{3\dfrac{d}{\delta}-2\dfrac{d^3}{\delta^3}}{2\left[1-\left(1-\dfrac{d^2}{\delta^2}\right)^{3/2}\right]} \tag{33}$$

where

$$\delta=\left(\frac{2H_0\rho}{\omega B_0}\right)^{1/2}$$

The value of the pf depends on the value of d/δ only. When d/δ is equal to or greater than unity, the power factor is 0.894, which is amply supported by the test values as shown in Table II. As d/δ decreases, the pf also decreases according to the foregoing equation, and the measured and the test values are in reasonable agreement.

* The losses are calculated for the total volume of the ring, which is 578 cubic centimeters.
† Thickness is more than twice the depth of penetration and hence Rosenberg formula for losses in thin plates is not applicable.

Iron Losses in Thin Laminations

Table III presents a comparison of eddy-current losses in thin laminations calculated by the new theory with those given by the theories of Dreyfus[8] and Rosenberg.[4] These theories are discussed in brief in Appendix II. These losses, according to formulas given by Rosenberg and Dreyfus, are proportional to the square of the peak flux density. This would mean that as we increase the applied mmf, the peak flux density, and therefore the losses, will increase until the iron becomes saturated, and then any increase in applied mmf will produce little increase in losses. This is contrary to all test results since tests show that the losses are a function of applied mmf. It can be seen from Table III that Rosenberg and Dreyfus values have errors which might go as high as 400%. The calculated values by the new theory are within 15% of the test values, except for low frequency and low applied mmf when hysteresis loss, which has not been included here, is not negligible.

Experimental Work

The first core-loss tests on 1-inch, 1/4-inch, and 1/8-inch steel-bar specimens were made by the General Engineering Laboratory, of the General Electric Company, in Schenectady. Tests were made at 30, 60, and 120 cycles up to an applied mmf of about 400 ampere-turns per inch, using a 50-centimeter Epstein frame. In this setup, it was difficult to determine accurately the mmf acting on the specimens alone, because of the air gaps at the butt joints. It was therefore decided to prepare ring specimens.

The following rings of outside diameter

12 inches and inside diameter 10 inches were cut out of common steel plate, General Electric material *B4A26* in the "as received" condition:

1. One ring from 1-inch steel plate.
2. Four rings from 1/4-inch steel plate.
3. Eight rings from 1/8-inch steel plate.
4. Sixteen rings from 1/16-inch steel plate.

The 1/4-, 1/8-, and 1/16-inch rings were individually dipped in a fine solution of shellac in alcohol, thus providing a very thin coating of shellac as insulation between the laminations. Rings of same plate thickness were then assembled together to give four rings of cross-section 1 by 1 inch and outside diameter 12 inches and inside diameter 10 inches. Each ring was covered by electrical scotch tape no. *33* with half overlap. Two search coils of 30 turns each were then wound on each ring at opposite ends. Then each ring was covered with about 225 turns of uniformly wound no. 12 American Wire Gauge heavy, Formex-coated copper wire. This was covered with one layer of electrical scotch tape, and another coil of about 75 turns was wound uniformly around the whole ring. Splitting the magnetizing winding into two coils gave the flexibility of using 225±75 turns, to adjust to the voltage and current available.

A second series of tests were made at the Polytechnic Institute of Brooklyn to determine iron losses in the ring specimens at frequencies of 15, 30, 45, 60, 75, and 90 cycles. Because of inadequate capacity of the machine available, it was not possible to maintain sinusoidal current at high values of mmf.

A third series of tests were made on the ring specimens in the General Engineering Laboratory. These tests were made at 30, 60, 120, 240, 480, and 2,000 cycles. Since the smallest generator used was 60 kva, it was possible to use a larger noninductive resistance, which absorbed by far the major portion of applied voltage, and thus it was possible to force the current to be sinusoidal. Photographs of the wave forms of current and search coil voltage were taken simultaneously. Every care was taken to obtain all readings at about room temperature. D-c magnetic measurements were made on the rings by the Rowland ring method, using a ballistic galvanometer.

Conclusions

It has been shown that the eddy-current loss theory presented here, based on a rectangular magnetization curve and sinusoidal impressed mmf waveform, provides a simple loss formula that checks very well with test results over a very wide range of frequencies, flux densities, and lamination thickness. Although the actual magnetization curve of iron departs from the ideal shape assumed in the theory, comparison of analytical and experimental waveforms of search coil voltage indicates that magnetization of the iron does actually take place as predicted by the rectangular theory.

The oscillograms show that in thin laminations at high values of impressed mmf with sinusoidal wave form, the flux rises to its saturation value in the first few degrees of the time cycle, and, thereafter, the flux remains almost constant until the end of the half-cycle. Hence, the eddy currents that oppose the rise of flux are intermittent, being large in the first part of each half-cycle and nearly zero after the flux reaches saturation. Thus, the effect of applied mmf beyond that required to produce normal magnetic saturation is to increase the rate of change of flux, giving the same effect as an increase in frequency. This explains why the fundamental frequency core losses in rotating machines rise so rapidly (as the sixth to seventh power of flux, approximately), when the apparent flux density is increased beyond normal saturation limits.

The theory applies to rotating machines especially, because their mmf waves that create the fundamental flux have nearly sinusoidal waveforms. Since in transformers, and many other applications, the total flux, and not the applied mmf, is sinusoidal, a formula for eddy-current losses in this case using the idealized saturation curves has been derived in the thesis, although no comparison with test results was made.

As far as the author is aware, no satisfactory formula, analytical or empirical, for calculating eddy-current losses when the mmf wave is nonsinusoidal, is available today. It is intended, therefore, to extend this work to include the effects of harmonics in the applied mmf.

Appendix I

Losses by Time Average Dissipation

As indicated in the text, since H is sinusoidal, the harmonics of E do not contribute to the power flow into the metal. This, at first thought, seems to be wrong because for nonsinusoidal current flow the power loss is the sum of losses caused by the fundamental and the harmonics. Here the case is different. The wave form of E, the value of electric field e at the surface, is shown in Fig. 7(A). The value and waveform of electric field are different at different depths from the surface. The function $e(Z, t)$, can be easily obtained from Figs. 6 and 7(A), and is shown in Fig. 15. The electric field e has the value E after ζ exceeds Z; otherwise zero.

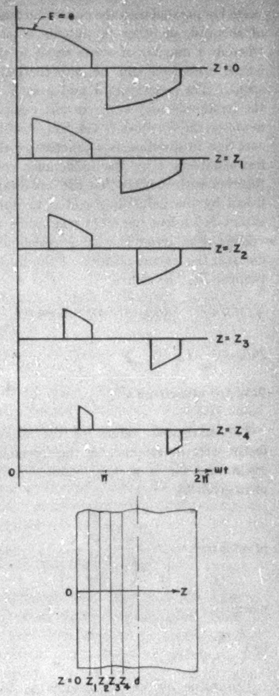

Fig. 15. Waveform of electric field at various depths from the surface

That the power loss is correctly given by equation 35

$$N=\frac{8}{3\pi}\frac{H_m{}^2}{\gamma\delta}\left[1-\left(1-\frac{d^2}{\delta^2}\right)^{3/2}\right]$$

can be verified by calculating the total dissipation

$$N=\int_0^d \gamma\langle e^2\rangle dz \tag{54}$$

where < > means time average.

$$\langle e^2\rangle=\frac{2}{T}\int_{\omega t=2\sin^{-1}z/\delta}^{\omega t=2\sin^{-1}d/\delta} E_{(t)}{}^2dt$$

$$\langle e^2\rangle=\left(\frac{2H_m}{\gamma\delta}\right)^2\frac{2}{T}$$

$$\int_{\omega t=2\sin^{-1}z/\delta}^{\omega t=2\sin^{-1}d/\delta}\cos^2\frac{\omega t}{2}\,dt$$

$$=\left(\frac{2H_m}{\gamma\delta}\right)^2\frac{1}{2\pi}\int_{2\sin^{-1}z/\delta}^{2\sin^{-1}d/\delta}\cos^2\frac{\theta}{2}\,d\theta$$

$$<e^2>=\left(\frac{2H_m}{\gamma\delta}\right)^2\frac{1}{2\pi}\left[2\sin^{-1}\frac{d}{\delta}+\right.$$

$$\left.\sin 2\sin^{-1}\frac{d}{\delta}-2\sin^{-1}\frac{z}{\delta}-\sin 2\sin^{-1}\frac{z}{\delta}\right]$$

$$=\left(\frac{2H_m}{\gamma\delta}\right)^2\frac{1}{2\pi}\left[2\sin^{-1}\frac{d}{\delta}+\right.$$

$$2\frac{d}{\delta}\sqrt{1-\frac{d^2}{\delta^2}}-2\sin^{-1}\frac{z}{\delta}-$$

$$\left.2\frac{z}{\delta}\sqrt{1-\frac{z^2}{\delta^2}}\right]$$

Substituting in equation 54

$$N=\gamma\left(\frac{2H_m}{\gamma\delta}\right)^2\frac{1}{2\pi}\int_0^d\left(2\sin^{-1}\frac{d}{\delta}+\right.$$

$$2\frac{d}{\delta}\sqrt{1-\frac{d^2}{\delta^2}}-2\sin^{-1}\frac{z}{\delta}-$$

$$\left.2\frac{z}{\delta}\sqrt{1-\frac{z^2}{\delta^2}}\right)dz$$

$$=\gamma\left(\frac{2H_m}{\gamma\delta}\right)^2\frac{1}{2\pi}\left[2d\sin^{-1}\frac{d}{\delta}+\right.$$

$$2d\frac{d}{\delta}\sqrt{1-\frac{d^2}{\delta^2}}-\left\{2z\sin^{-1}\frac{z}{\delta}+\right.$$

$$\left.\left.2\sqrt{\delta^2-z^2}-\frac{2\delta}{3}\left(1-\frac{z^2}{\delta^2}\right)^{3/2}\right\}_0^d\right]$$

$$=\gamma\left(\frac{2H_m}{\gamma\delta}\right)^2\frac{1}{2\pi}\left[\frac{4\delta}{3}+2d\frac{d}{\delta}\sqrt{1-\frac{d^2}{\delta^2}}-\right.$$

$$\left.2\delta\sqrt{1-\frac{d^2}{\delta^2}}+2\frac{\delta}{3}\left(1-\frac{d^2}{\delta^2}\right)^{3/2}\right] \quad (55)$$

$$N=\gamma\left(\frac{2H_m}{\gamma\delta}\right)^2\frac{1}{2\pi}\left[\frac{4\delta}{3}-2\delta\left(1-\frac{d^2}{\delta^2}\right)^{1/2}+\right.$$

$$\left.2\frac{\delta}{3}\left(1-\frac{d^2}{\delta^2}\right)^{3/2}\right]$$

$$=\gamma\left(\frac{2H_m}{\gamma\delta}\right)^2\frac{1}{2\pi}\left[\frac{4\delta}{3}-\frac{4\delta}{3}\left(1-\frac{d^2}{\delta^2}\right)^{3/2}\right]$$

$$=\frac{8}{3\pi}\frac{H_m^2}{\gamma\delta}\left[1-\left(1-\frac{d^2}{\delta^2}\right)^{3/2}\right] \quad (35)$$

Appendix II

The Theory of Dreyfus[6]

An important factor in the theory is the "reduced thickness" $\xi=\alpha h$ of the lamination, where h is the thickness of the lamination in millimeters.

$$\alpha=2\pi\sqrt{\nu\mu\lambda 10^{-5}} \quad (56)$$

ν=frequency of applied mmf
μ=permeability$=\frac{1}{0.4\pi}\frac{B}{\sqrt{2}H}$
B=flux density in gausses, corresponding to $\sqrt{2}H$
H=magnetic field intensity in ampere turns per cm (centimeter), rms
λ=conductivity in ohms per meter and millimeter

The distribution of eddy currents is similar for all laminations with the same reduced thickness ξ. This quantity has no dimension and is porportional to the ratio of the inductive to the ohmic resistance of the paths in which the eddy currents flow. Calculations show that ξ lies between 0.2 and π, and that the greater the value the more the field is concentrated toward the edges of the lamination, and the more the phase of the field in the middle lags behind the phase at the edge of the lamination. The eddy-current loss in watts per decimeter^3 is given as

$$\frac{W^{\mathrm{watt}}}{V^{\mathrm{cdm}}}=\left(\frac{\pi^2\lambda}{10\times 6}\right)f_\rho\left[\frac{\nu}{100}\frac{B_m}{1000}h^{\mathrm{mm}}\right]^2 \quad (57)$$

B_m is the mean flux density over the section of the lamination

$$B_m=B_{h/2}\frac{\sqrt{2}}{\xi}\sqrt{\frac{\cosh\xi-\cos\xi}{\cosh\xi+\cos\xi}} \quad (58)$$

where $B_{h/2}$=amplitude of flux density at the edges.

For small values of ξ

$$B_m\approx B_{h/2}\left[1-\frac{1}{3}\left(\frac{\xi}{2}\right)^4\right]$$

and for $\xi\geqslant\pi$

$$B_m\approx B_{h/2}\frac{\sqrt{2}}{\xi}$$

f_ρ is a factor to allow for the reaction of eddy currents on the inducing field, and is given by

$$f_\rho=\frac{3}{\xi}\frac{\sinh\xi-\sin\xi}{\cosh\xi-\cos\xi} \quad (59)$$

For $\xi<3.5$ we have approximately $f_\rho=1-0.0014\xi^4$ and for $\xi>3.5$ we have $f_\rho=3/\xi$. Curves giving the value of f_ρ and the ratio $B_m/B_{h/2}$ as a function of ξ are given for values of ξ up to 9.

The Theory of Rosenberg[4]

Rosenberg presented a separate formula for the eddy-current losses in "thin plates" whose thickness is less than twice the penetration depth, so that the total of their eddy currents is materially smaller than the exciting ampere-turns. The loss per cubic cm in watts is

$$L_{\mathrm{ccm}}=1.64(10^{-16})\frac{f^2B^2d^2}{\rho} \quad (60)$$

where

f=frequency of applied mmf
B=peak flux density at surface in lines per cm^2
d=lamination depth in cm
ρ=resistivity in ohms per cm and cm^2

Discussion

Dr. Ernst Weber (Polytechnic Institute of Brooklyn, Brooklyn, N. Y.): Professor Agarwal's ingenious extension of Professor MacLean's earlier work on eddy-current losses in solid iron constitutes a very significant contribution in a field which was already intriguing to J. J. Thompson. The replacement of the magnetization curve by its rectangular idealization has been fully exploited here, and the reward is a rather clear and incisive picture of the peculiar distribution of eddy currents, limited in space in solid iron (MacLean), and limited in time in iron laminations where the depth of penetration is larger than half the thickness (Agarwal). In combination, the result is surprising agreement between measured and calculated values of eddy-current losses over wide ranges of frequency and magnetization values. Of course, one must accept a heuristic equivalent field value 0.75 $B_{\max}$ which cannot be theoretically deduced but which apparently serves to account for the finite slope of the magnetization curve above the knee of saturation.

It is surprising that agreement between measured and calculated losses exists down to H_{max} of the order of 20 ampere-turns per inch; however, almost all types of steel sheets and plates have their knees of saturation below this value of magnetization except cast iron. It would be interesting to check the theory in case of cast iron and also down to 5 and 10 ampere-turns per inch, though this would be more of academic interest than of practical value.

Another point of interest would be the case of pulsed magnetic excitation such as often found in magnetic amplifiers where the knowledge of losses is of considerable importance.

P. L. Alger (Rensselaer Polytechnic Institute, Troy, N. Y.): This paper marks a very important advance in our knowledge of eddy-current behavior in laminated steel. The paper shows that the eddy currents that occur in the laminations of rotating machines are intermittent, instead of being continuous as always assumed heretofore. That is, the eddy currents which oppose the flux change in a particular lamination rise rapidly at the start of each half-cycle, then decrease to a very small value during most of the cycle, and rise again at the end of the half cycle.

This occurs because the mmf impressed on the magnetic circuit of a rotating machine varies sinusoidally in time, in accordance with the sinusoidal distribution of the current around the periphery of the machine. Thus, for a given high value of flux density, the impressed mmf at the start of a cycle is much larger than necessary to produce a sinusoidal flux. These conditions are very different from those in a transformer, where the exciting current has a highly peaked waveform, and the mmf is, therefore, low at the start of each cycle.

The formulas developed in accordance with this new understanding are extremely simple and practical, while at the same time they cover the full range of frequency, steel thickness, and flux density, so long as the mmf has a sinusoidal waveform in time.

The discusser is sure that the ideas presented in the paper, when combined with the physicist's ideas of domain theory, will lead to further important advances in the understanding of eddy-current phenomena in transformers and all sorts of apparatus.

G. Angst (General Electric Company, Schenectady, N. Y.): This paper represents a valuable contribution to the theory of eddy-current calculation in solid iron and in laminated magnetic structures. The worth of the paper is enhanced by the close agreement between calculations and test results.

It has been known to designers of rotating electric machinery for some time that the classical formula for eddy currents in laminated cores breaks down when the magnetic flux density is increased beyond normal peak values of about 100 kilolines per square inch. Experimental evidence has shown that the fundamental frequency eddy-current losses increase with the sixth power of the flux density instead of the second power. The author's analysis predicts and explains this phenomenon satisfactorily. It is believed that the theory, when applied to high-frequency core losses due to harmonics, should also result in closer agreement between prediction and test.

In the field of solid-iron application the author's study has contributed considerably to a better understanding of the physical phenomena involved. Doctor Agarwal has limited himself to the solution of the two-dimensional problem. In rotating machines with solid iron rotors, end effects may become important. This then presents a three-dimensional field problem and it is hoped that further studies will be made in this area, leading to a satisfactory solution.

E. F. Hansen (General Electric Company, Schenectady, N. Y.): The author has made an outstanding contribution to electrical engineering by developing and presenting this new and more accurate method of predicting eddy-current core loss in ferromagnetic materials as used in rotating electric machinery.

Any engineer concerned with design and performance testing of electric machinery will testify that the need for better methods of calculating core loss goes back many decades. The laboratory engineer or scientist active in development or testing of magnetic materials for rotating machinery will also be aware of the lack of correlation between core loss measured in the laboratory and core loss measured on actual tests of machines. The new method, properly applied, should help to remove those errors in the calculation of core loss attributable to eddy-current loss at fundamental frequency of mmf.

This paper will very likely be of practical use not only in calculating core losses of rotating electric machinery but also in other laminated magnetic circuits such as solenoids and a-c lifting magnets. Other indirect applications would be where eddy currents in solid or laminated iron dictate the time constants of field windings. There are other cases where eddy currents in rotating solid iron pole faces serve the useful function of damping out torsional vibrations. The author mentioned several other applications.

A quite different application would be the induction heating of ferromagnetic materials. The sine wave of applied mmf would be representative of most core-type induction heating fixtures.

The inherent accuracy of the new method is demonstrated by excellent agreement with the author's experimental test results. This is even more gratifying when compared to the substantial errors possible when calculations were made using the previously available methods.

It seems to the discusser that the author's work also demonstrates the way in which progress often results from a change in point of view. Many engineers have always thought of eddy-current loss as a function of flux density when in reality there seems to be considerable advantage in considering it as a function of magnetizing current. This concept is multiplied in importance because the sine wave of mmf is more likely to occur in magnetic circuits with air gaps than the sine wave of flux. Since the air gap is a significant factor in rotating electric machinery, the concept of eddy-current loss as a function of a sine wave of mmf is quite appropriate.

On the other hand, since pure sine waves of mmf would be rare, the author's proposal to investigate the effect of harmonic currents is to be encouraged. A further suggestion, for the benefit of those of us who for so long have been thinking in terms of sine waves of flux, would be to further clarify the relationship of the losses encountered with the sine wave of current as compared to the sine wave of flux. This paper should be an inspiration to encourage students to enter the field of electrical power engineering. There are still many, many more new areas of discovery not yet uncovered.

H. Poritsky (General Electric Company, Schenectady, N. Y.): The type of analysis given in this paper should be welcomed by the electrical industry. The analysis is based on the arbitrary assumption that the flux density is constant and equal to $3/4B_m$. Yet the fair agreement of the predicted losses with measured values serves to justify the assumptions made.

Generally, the flux which penetrates a magnetic lamination or a solid portion of a motor or generator is not driven by a uniform, tangential magnetic field. The flux may take a path which is partly in the metal, partly in air, and the metallic portion may be subject to different degrees of saturation. An analogous situation is given by a ring in which the windings are not uniformly distributed, and the ring is not complete.

Even if one simplifies the problem to that of a uniformly continuous winding over a solid ring, the winding to be fed directly by a generator, the applied mmf will be sinusoidal only if there is a large external resistance in the circuit. If the resistance of the winding and generator impedance are small, then the emf will be sinusoidal. In intermediate cases the voltage equation for the circuit of the winding may result in a more complicated condition at the ring surface than either sinusoidal mmf or sinusoidal emf.

For the foregoing reasons, it is desirable that a direct solution of Maxwell's equations with general boundary conditions be worked out. If E denotes the induced electric field, then Maxwell's equations lead to simultaneous equations (in centimeter-gram-second practical units)

$$\frac{\partial B}{\partial t}=10^{-8}\frac{\partial E,}{\partial z}, H=H(B) \tag{61}$$

$$\frac{\partial H}{\partial z}=\frac{4\pi}{10}I=\frac{4\pi}{10}\lambda E \tag{62}$$

or eliminating E

$$\frac{\partial B}{\partial t}=4\pi\lambda 10^{-9}\frac{\partial^2 H}{\partial z^2} \tag{63}$$

For a sinusoidal mmf the value H at $z=0$ is sinusoidal in time. For sinusoidal emf E at $z=0$ is sinusoidal in time. If there is a significant resistance in the winding circuit, then the boundary condition involves both H and E at $z=0$.

The solution of differential equations 61 and 62 is quite involved analytically. This discusser has tried several methods of approach, all of which turned out to be complex. He has also used direct numerical methods based upon introducing a finite grid of points in the (z, t)-plane, at the same time replacing the derivatives by finite differences. He hopes to present these methods at a future occasion.

Both the analytical and the numerical methods are time consuming. Yet with the advent of high-speed computing machines they become economically feasible.

Frederick J. Young (Carnegie Institute of Technology, Pittsburgh, Pa.): The author uses Maxwell's equations in conjunction with the idealized magnetization curve of Fig. 1 to derive expressions for eddy current losses in iron. This assumption, if taken literally, leads to an inconsistency. The tangential component of E at the moving surface is discontinuous. This consequence of the idealized treatment has been recognized by McConnell.[1]

Really McConnell's earlier treatment (vaguely mentioned in the author's reference 3) is remarkably similar to that of this paper in the matter of assumptions, methods, and conclusions. Perhaps the contribution of the author should have been stated more explicitly.

REFERENCE

1. EDDY-CURRENT PHENOMENA IN FERROMAGNETIC MATERIALS, H. M. McConnell. *AIEE Transactions*, vol. 73, pt. I, July 1954, pp. 226–34.

Paul D. Agarwal: The interest shown in this paper by the discussers is very encouraging and the author wishes to thank them for their contribution. It is gratifying to note that they recognize the value of the formulas and the data presented in this paper, and the need for further work in the field.

Dr. Weber's suggestion of checking the theory for values of magnetization below the knee of the saturation curve presents a formidable difficulty. At these low values of magnetization the hysteresis loss is predominant, and the division of the total measured losses into eddy-current losses and hysteresis losses depends on the empirical formulas used. The accuracy of these formulas, and hence the division of experimental losses, is questionable. Therefore, comparison of eddy current-losses at these low densities loses significance. Dr. Weber's idea of extending this work to magnetic amplifiers is an excellent one.

Mr. Alger's suggestion of combining this work with the physicist's ideas of domain wall theory of magnetization is indeed valuable. The author has already been working on this possibility and hopes to present some results in the not-too-distant future.

Eddy-current losses in laminated cores, according to most formulas in use today, are proportional to the square of the peak flux density. This would mean that as the applied mmf is increased, the peak flux density and hence the eddy current losses, will increase until iron is saturated. Beyond this any increase in applied mmf will produce little increase in losses. This is contrary to all test results presented in the paper, which show that losses are a function of applied mmf. Mr. Angst points out that the theory presented in this paper satisfactorily explains the fundamental frequency eddy-current losses in rotating machines, which experiments show, rise as the sixth to seventh power of flux density when flux density is increased beyond 90–100 kilolines per square inch. Solid-iron rotors in which end effects are not minimized by either copper end rings or extension of rotors beyond the stator stacks present a difficult problem. The extension of the theory to this three-dimensional field problem would indeed be a useful investigation. At this time the author wishes to acknowledge the benefit that he has derived from his discussions with Mr. Angst during their association at the General Electric Company.

Mr. Hansen points out how progress often results from a change in point of view. The theory presented here has brought out two new concepts which are contradictory to views presently held.

1. That eddy-current losses should be considered a function of mmf and not of flux density.

2. That in thin sheets eddy currents flow intermittently and not continuously.

Both the new concepts are, however, correct, as amply supported by experimental data. The author is glad Mr. Hansen mentions the need for encouraging students to enter the field of electrical power engineering. From the author's point of view this cannot be stressed enough. The number of young men entering this field has been decreasing rapidly with every year and the situation has become alarming.

Dr. Poritsky's discussion gives an opportunity to elaborate on some of the points brought out in the paper. It is recognized that as we penetrate into the material, each succeeding inner layer is magnetized by a progressively smaller number of exciting ampere turns because of the shielding effect of the eddy currents in the region between the outside surface and the layer under consideration. But because of the assumed ideal magnetization curve the flux density wave has the same magnitude irrespective of the magnitude of mmf. It is the departure of the actual B-H curve from the ideal assumed that has necessitated the factor 3/4 as explained in the section "Flux Density B_0" and in Fig. 10. That the magnetization does seem to take place as if waves of constant flux density were penetrating the material is substantiated by comparison of experimental and analytical waveshapes of search coil voltages presented in Fig. 11. The author agrees with Dr. Poritsky that in many applications neither the applied mmf nor the total flux is sinusoidal and it is pointed out in the conclusions of the paper that the work needs to be extended to include the effects of harmonics in the applied mmf. A rigorous solution of Maxwell's equations for nonsinusoidal mmf and using the B-H relation presented by the actual hysteresis loop will be a great analytical accomplishment. However, the practical value of such a solution is questionable. Since in samples from the same material the value of H for the same value of B may vary $\pm 15\%$, it is the author's opinion that an exact solution of the problem with its enormous complexity is not warranted.

Table IV. D-C Magnetization Data on 1/4-Inch Ring Specimen

Resistivity, 14.4 Ohm-Cm

H, Ampere-Turns/Inch	B, Kilolines/Inch^2
8	44.0
16	71.5

120	104.6
160	107.5
240	112.7
320	116.6
400	119.2

That the assumption of the idealized magnetization curve leads to discontinuous E at the separating surface, though obvious from the field pictures presented, needs further explanation according to Mr. Young's discussion. The separating surface is at the wavefront $h=0$, at which point the permeability is infinite according to Fig. 1. This is a technique often followed in an effort to simplify the solution; i.e., the problem is first idealized, and then the solution is examined for corrections required because of departure from idealization. That is why it is mentioned in the paper that "In comparing the theoretical and experimental waveforms, it should be kept in mind that the actual magnetization curve is not exactly rectangular, and therefore no sharp corners should be expected in the experimental waveforms of the search coil voltages." This immediately removes the inconsistency mentioned by Mr. Young.

Mr. Young's attention is directed to the last paragraph in the opening paragraphs, where it is clearly stated that several authors (including McConnell) have solved the solid-iron case under the assumption of a rectangular magnetization curve. It was not considered necessary to name each author. The last sentence in the opening section reads "However, so far as the author is aware, no previous writer has derived the formulas for the laminated iron case that are developed here. Nor have any authors obtained satisfactory checks between calculated and test results over so wide a range of applied mmf, frequency, and plate thickness as are covered here." Mr. Young should have found this an explicit statement of the author's contribution.

During the presentation of the paper at the Winter General Meeting of the AIEE in New York, information was requested on the magnetization curve of the ring specimens used. Although the B-H curves of various specimens were slightly different, the values given in Table IV are fairly representative.

A Method for Calibration of Precision Voltage Dividers

CHARLES B. PINCKNEY
ASSOCIATE MEMBER AIEE

ONE PHASE of electrical measurements which is rapidly becoming more important and requiring higher degrees of accuracy is the measurement of voltage ratio. Conventional 4-arm bridge techniques are often used where two impedances are connected in series, energized from either or both of the voltages whose ratio is being measured, and adjusted so that the voltages across them exactly match the two being compared, both in magnitude and phase angle. The voltage ratio can easily be computed if the characteristics of the impedances are known. Sze has developed a system which uses this technique and will measure voltage ratio with an accuracy of about 50 parts per million (ppm) and phase angle to 0.2 minute at frequencies up to 10,000 cycles per second (cps).[1]

A device which lends itself well to measurements of ratio is the voltage divider, often referred to as a potentiometer. According to strict definition, it is not a potentiometer, but usage of the term is fairly common and is used here for clarity. In any case, it is a tapped impedance, presenting a voltage at its output terminals which is equal to or less than that applied to its input terminals, depending upon the position of the tap. This position may be calibrated to indicate the ratio of the output to the input voltage; a decimal fraction or percentage scale is often convenient. Such a scale must be evaluated and any resulting corrections taken into consideration if the voltage divider is to be used for accurate measurements. It should be noted that varying degrees of loading at the output terminals will affect these corrections, and a common practice is to specify open-circuit conditions.

If the voltage divider has continuous resolution or is adjustable in very small finite steps, it is obviously impracticable to provide corrections for every possible reading of the scale. It is often satisfactory to calibrate only the points which are used most frequently, or to calibrate the main, or cardinal points, 0.1, 0.2, 0.3, etc. The corrections may be determined in two ways: set the divider on the exact point to be calibrated and adjust the voltage ratio to coincide, or measure a known fixed voltage ratio with the divider. In either case, the correction to be applied to the divider is the difference between the true ratio and that indicated by the divider.

The purpose of this paper is to describe a technique which may be used to establish known fixed ratios on a voltage divider, which may then be used as a standard for the calibration of others. The method was investigated using a type of voltage divider which is basically an autotransformer, but the theory applies equally well to resistive and capacitive dividers.

Theoretical Considerations

A perfect voltage divider providing ratios in steps of tenths would consist of 10 sections with identical impedances. The absolute values of these impedances need not be known, but each section would have a relative value of exactly 0.1 If the divider was not perfect, the relative values would differ more or less from 0.1, but in any case their sum must equal unity, since the output cannot exceed the input voltage. The ratio presented at any of the taps is the sum of the relative values of the sections involved.

The impedance ratio which can be measured most accurately is that of unity, that is, when the two impedances are identical. This principle may be used to determine the relative values of the voltage divider sections, using a variation of a technique which was developed at least as long ago as 1915.[2] A precision ratio transformer was developed by B. Diener, of Hughes Aircraft Company, also using a variation of this technique, in an independent study. If the ratio of each section to the section immediately below it in the divider is measured, section 10/section 9, section 9/section 8, etc., the results may be combined by a simple algebraic manipulation to express each section in terms of a common reference, say section 1. For example

$$\frac{\text{section 4}}{\text{section 1}}=\left(\frac{\text{section 4}}{\text{section 3}}\right)\left(\frac{\text{section 3}}{\text{section 2}}\right)\left(\frac{\text{section 2}}{\text{section 1}}\right)$$
$$=K_4$$
$$\text{section 4}=K_4(\text{section 1})$$

As previously stated, the sum of the relative values of the sections must equal unity.

$$\text{section 1}+\text{section 2}+\ldots+\text{section 10}=1$$

Substituting for each section its equivalent value in terms of section 1

$$\text{section 1}+K_2(\text{section 1})+\ldots+K_{10}(\text{section 1})=1$$

Solving for the relative value of section 1

$$\text{section 1}=\frac{1}{1+K_2+\ldots+K_{10}}$$

The relative value of each section may be calculated from the relative value of section 1 and the corresponding value of K.

If the standard divider is constructed so that section 1 is further subdivided into 10 smaller sections, these sections can be evaluated in the same manner and used to provide voltage ratios from 0.01 through 0.09. In this case, however, the sum of the relative values is equal to the relative value of section 1 rather than unity. Theoretically, this process could be carried on indefinitely, but in practice the reduction in allowable voltage (and the corresponding decrease in sensitivity) limit the calibrations to the second or third decades for most cases.

The validity of the measured relative values of the sections can be tested by using various combinations of sections to produce a ratio approaching unity. The measured ratio of (section 1+section 2)/(section 3+section 4) should equal the ratio of this combination as calculated from the relative values. This applies to any number of sections when compared to an equal number of adjoining sections.

Other ratios may be set up for measurement by using less than 10 sections for the standard divider, recalculating the relative values accordingly. If 9 sections are used, ratios in multiples of 1/9 are established, 0.1111111, 0.2222222,

---

Paper 59-22, recommended by the AIEE Special Instruments and Auxiliary Apparatus Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1-6, 1959. Manuscript submitted February 10, 1958; made available for printing November 14, 1958.

CHARLES B. PINCKNEY is with the Hughes Aircraft Company, Culver City, Calif.

The author wishes to express his appreciation to the Primary Standards Laboratory, Hughes Aircraft Company, for the facilities made available and for encouragement in the preparation of this paper.

Vol.
Pt. 1
1959

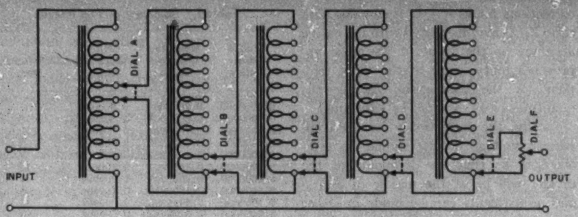

Fig. 1. Diagram of ratio transformer type of voltage divider

0.3333333, etc. This procedure also serves as a cross check for the relative values, since certain ratios can be set up by using different combinations of sections. A ratio of $^1/_3$ can be established by using 3 sections of a 9-section divider, 2 sections of a 6-section divider, or 1 section of a 3-section divider.

The possibility exists that the ratios presented by the standard will be too high or too low to be used for calibrating the desired point on another divider. For example, the sum of the relative values of 6 of the standard sections might be 0.5999980, which could be too low to be measured using the 0.6 setting of the divider to be calibrated. If necessary, the characteristics of the standard can be altered by adding a small series impedance to either end and including it in the relative value measurements. If impedance is added to the bottom of the standard divider, it will be included in the relative value of section 1 and all the taps will be shifted upward in value.

The foregoing arguments are based entirely on considerations of impedance magnitude. While this analysis is valid for measurements made with direct voltage, the quantities involved with alternating voltage are related in phase as well as magnitude and must be treated accordingly. Excessive phase shifts in voltage dividers are usually undesirable, however, and a well-designed divider will have little or none within the frequency range of normal use. Typical values for the units used in this investigation are of the order of 0.1 minute at 1,000 cps. The error in magnitude introduced by adding phasors directly, without regard to phase angle, is less than one ppm for angles smaller than 3 minutes. A phase angle will cause a reduction in bridge resolution, however, since the quadrature component of the unbalance signal is still present in the detector after the real component is balanced, and this may affect the amount of phase shift which can be ignored.

Description of Tests

Voltage Dividers Used

Voltage dividers of the type known as ratio transformers were used in all of the tests performed. They are basically autotransformers, with a switching arrangement based on a variation of the Kelvin-Varley circuit, which provides continuous adjustment through a succession of paralleling decades; see Fig. 1. The Kelvin-Varley circuit applies to resistive voltage dividers and requires 11 sections per decade, with the paralleling decades shunting 2 sections at a time so as to form 10 equivalent sections. The ratio transformer uses 10 sections per decade. The windings are on a common core, and the paralleling decades contain the same number of turns as the section across which they are connected, so that a voltage is induced in the windings of the paralleling decades equal to that in the bridged section and no loading takes place. A separate core is used for the fourth and fifth decades to reduce the number of turns necessary for the first decade, but the loading effect of the second core seems to be negligible.

The validity of the arguments which have been presented was tested by calibrating a number of voltage dividers by intercomparison of their component sections. In the discussion which follows, when the term "standard" voltage divider is used, the reference is to these units. The standard dividers were used to determine corrections for a similar divider which had been calibrated by the National Bureau of Standards using Sze's apparatus and technique; this unit is referred to as the "test" voltage divider. The divider used for calibration of the standards is designated the "comparison" divider; see Fig. 2.

Calibration of Standard Dividers

The ratio of each section in the standard to the section immediately below it was measured with the comparison divider, as shown in Fig. 2, and these measurements used to calculate the relative value of each section in the manner which has been described. The final accuracy of the calibration of the standard is largely dependent upon the accuracy with which the ratios of adjacent sections can be measured. The following discussion indicates that the closer the standard is to being perfect (all sections identical), the more accurate the calibration of it.

The circuit diagram of the ratio transformers used in these tests is shown in Fig. 1. The ratio of output to input voltage is read directly from the dials of the switches controlling the various paralleling decades. Dials A, B, C, D, and E are scaled from 0 to 9. Dial F is scaled from 0–100. If the corrections for the dials are designated a, b, c, d, e, and f, the true ratio for any setting is given by

$$R_t = 0.1(A+a)+0.01(B+b)+0.001(C+c)+0.0001(D+d)+0.00001(E+e)+0.0000001(F+f) \quad (1)$$

If the ratio transformer is used to measure the ratio of Z_1 to Z_2, as shown in Fig. 3, and Z_1 and Z_2 are identical, the resulting bridge circuit will balance at the same setting of the ratio trans-

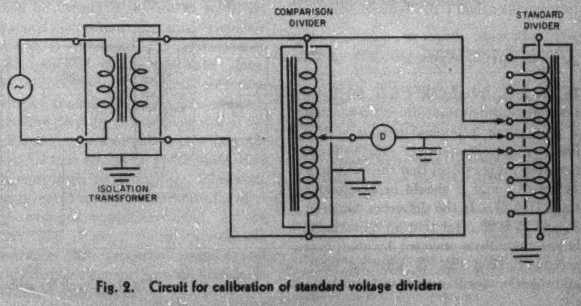

Fig. 2. Circuit for calibration of standard voltage dividers

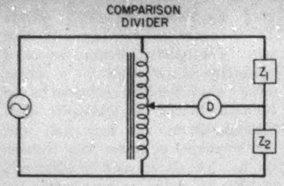

Fig. 3. Measurement of the ratio Z_1/Z_2

former whether Z_1 and Z_2 are connected as shown or interchanged, since the setting represents the exact midpoint of the comparison divider. If Z_1 and Z_2 have slightly different values, the divider will require adjustment for balance on direct and reversed connections. Assuming for the moment that the adjustment is small enough to be made entirely with dial F, the settings and corrections of dials A, B, C, D, and E will remain the same and may be combined for convenience.

Let

R = combined settings of dials A, B, C, D, and E
r = combined corrections a, b, c, d, and e
F, F' = settings of dial F for direct and reversed connections
f, f' = corrections to dial F at F and F'

With Z_1 and Z_2 connected as shown in Fig. 3

$$\frac{Z_1}{Z_2}=\frac{1-(R+r+F+f)}{(R+r+F+f)} \qquad (2)$$

With Z_1 and Z_2 interchanged:

$$\frac{Z_1}{Z_2}=\frac{(R+r+F'+f')}{1-(R+r+F'+f')} \qquad (3)$$

Typical values for the quantities in equations 2 and 3 are:

$R=0.50000$
$r=3(10^{-6})$
$F,F'=5(10^{-6})$
$f,f'=1(10^{-7})$

If equations 2 and 3 are averaged and terms smaller than $1(10^{-10})$ discarded:

$$\frac{Z_1}{Z_2}=\frac{R}{R+(F+f)-(F'+f')} \qquad (4)$$

In the ratio transformers used for these tests, the adjustment controlled by dial F is a 5-ohm 3-terminal resistor with a linearity specification of 1%. From equation 1 it is evident that the maximum values of f and f' should be no greater than $1(10^{-7})$. If the difference between Z_1 and Z_2 is so great that an adjustment larger than that provided by dial F is necessary, then dial E must be used, and equation 4 will contain the additional corrections e and e'. It is obvious that ratio Z_1/Z_2 may measured with increasing accuracy as the value of the ratio approaches unity, since at the exact midpoint of the comparison divider the quantities $(F+f)$ and $(F'+f')$ are equal.

Ideally, the correction r for the comparison voltage divider should be −0.0000050, so that the midpoint of the divider will be at the middle of dial F and adjustments can be made in either direction for direct and reversed connections of Z_1 and Z_2. The reading corresponding to the midpoint will be 0.5000050, and the ratio Z_1/Z_2 can deviate from unity by as much as 20 ppm and still be measured using only dial F. The midpoint of the comparison divider used in these tests was at a setting of about 0.5000033, which provided sufficient leeway. If necessary, this midpoint can be shifted by the addition of impedance to either end of the comparison divider.

The standard dividers were removed from their cases so that connections could be made to the various sections; these taps are available at the switch contacts. Contact resistance at these points will affect the measurements and care must be taken to avoid this source of error. It was also found that the calibration of a standard is affected slightly by the position of the paralleling sections, possibly due to distributed capacitance effects. Thus, the corrections obtained for a standard divider are invalid at the conventional output terminals, since the only way to obtain the desired ratio at these terminals is to move the paralleling sections. The calibration is valid at the switch contacts as long as the paralleling sections are in the position of calibration, wherever it may have been. Data taken for one of the standard dividers indicates that the calibration of a given point was affected by 20 ppm or more by the position of the paralleling decades.

Table I. Summary of Test Results

Voltage Divider Setting	Measured Voltage Ratio	NBS Certified Ratio	Difference, Ppm
0.9000000	0.9000004	0.90000	<11
0.8000000	0.8000006	0.80000	<13

POWER SOURCE

Power for the measurements was supplied from a stable audio oscillator through a shielded and balanced isolation transformer. All of the measurements listed in Table I were made at 1,000 cps; this was the specified upper frequency limit of the test voltage divider. Exploratory data were taken at frequencies of 60 and 400 cps, and the results compared favorably with those observed at 1,000 cps. Voltages of about 2 volts per standard divider section were used, but it was found that voltage level had little effect on the results as long as the manufacturer's ratings were not exceeded.

DETECTOR SYSTEM

The detector system consisted of a battery-powered amplifier with a voltage gain of more than 10,000, the output of which was applied to an oscilloscope for visual presentation. Extreme selectivity was obtained in the amplifier by the use of twin-T filters. Phase shift in the voltage dividers reduce the resolution to about 2 ppm in extreme cases, but this was compensated to a large extent by using a technique of adjusting the voltage divider for equal amounts of

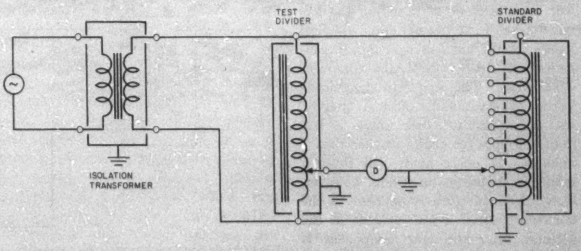

Fig. 4. Circuit for calibration of test voltage divider

unbalance signal on either side of the minimum and taking the midpoint of these settings as the null value. Tests were made using a mutual inductor to introduce a quadrature voltage into the detector circuit so that a complete balance could be reached, but the results were substantially the same, and it was felt that the system should be kept as simple as possible with a minimum of equipment. Over-all resolution of better than 0.5 ppm was achieved.

SHIELDING AND GROUNDING

Coaxial leads were used for all connections in the circuits. Various systems of shielding were tried, as was a Wagner ground. The Wagner ground had no apparent effect on the results and was not used for most of the tests. In the final tests, shielding was confined simply to grounding the cases of all equipment. Where the voltage dividers used as standards were removed from their cases to make connections to the taps, the shields around the cores and windings were grounded.

Results of Tests

In order to test the repeatability of the system, six different units were calibrated at 1,000 cps for use as standard voltage dividers. These were used to determine corrections for a test voltage divider which had been calibrated at the National Bureau of Standards (NBS) using Sze's apparatus and technique. The results for the six separate tests were in agreement with each other within eight ppm or better, and the deviation of their average from the calibration performed at the NBS is shown in Table I. The over-all accuracy of 0.005% for Sze's circuit is a general specification covering voltage ratios from 1 to 0.01 and frequencies up to 10,000 cps, and it is thought to be much better under some of the conditions for which these data are compared. For example, at 1,000 cps, the accuracies for ratios of 0.1 and 0.5 are believed to be 20 and 5 ppm, respectively.

Investigations are in progress at the NBS which will enable voltage ratios to be measured with much greater accuracies than are now possible. A capacitive voltage divider will be used in conjunction with a ratio transformer especially constructed by the NBS and accuracies of better than one ppm are anticipated.

It is hoped that when these facilities are available, they will provide a more precise evaluation of the system just described.

Conclusions

A system has been developed for the calibration of precision voltage dividers, based on the extreme accuracy with which equal or nearly equal impedances may be compared. A voltage divider is calibrated by intercomparison of its component sections and then used as a standard for the calibration of other dividers. Investigations were made at frequencies up to 1,000 cps, and accuracies of 0.01% or better were obtained for voltage ratios from 0.01 through 0.09 in steps of hundredths and from 0.1 through 0.9 in steps of tenths. See Fig. 4.

Calibrations performed on a voltage divider agreed with data furnished by the NBS within 30 ppm or better. The accuracy of the NBS calibration is estimated to range from 5–50 ppm, depending on the exact ratio.

Evaluation of Solderless Wrapped Connections for Central Office Use

S. J. ELLIOTT
ASSOCIATE MEMBER AIEE

SINCE 1952, when the solderless wrapped connection first was described publicly,[1] its use in telephone central offices has grown steadily. Several hundred million solderless connections are being wrapped annually in the Bell System today, and the growth is continuing.

The tangible and immediate results of solderless wrapping have been gratifying. For example, the use of solderless wrapping has reduced manufacturing costs by speeding up many wiring operations and by reducing troubles caused by wire clippings and solder splashes. Furthermore, since solderless wrapping avoids the risk of damaging heat-sensitive insulation by soldering operations, it has made widespread use of plastic insulated wire practicable, and this is leading to substantial additional savings.

In the end, however, these savings could be illusory if the use of solderless wrapped connections degraded telephone service or increased the maintenance effort required in the telephone plant. The laboratory evalution of solderless wrapped connections has been continued, therefore, in order to assess the risk of deterioration in service and to provide guidance for the design of connections that are most likely to be reliable. This work has revealed certain limitations of solderless wrapped connections, but, at the same time, it has provided considerable assurance that properly designed and properly made connections will be reliable in central office service.

Many persons have inquired about the methods used for evaluating the capabilities of solderless wrapped connections and about the results that have been obtained since publication of earlier papers.[2,3] Since the inquiries continue undiminished year after year, it appears that there is sufficient interest in solderless wrapping to warrant another paper on the subject. An attempt is made in this paper therefore to bring the story on evaluation up to date.

Description of Connection

A solderless wrapped connection is made by wrapping a wire tightly around a

Y., February 1–6, 1959. Manuscript submitted October 29, 1958; made available for printing November 20, 1958.

S. J. ELLIOTT is with the Bell Telephone Laboratories, Inc., New York, N. Y.

Many persons, working in several closely knit teams, have participated in the development of solderless wrapped connections. Each of those persons has played an important part in the development. In particular, the author wishes to acknowledge the contributions of H. L. Coyne and R. H. Van Horn, who supervised the several phases of the evaluation program.

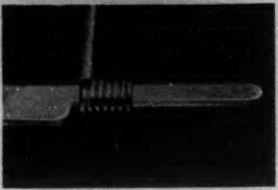

Fig. 1. Typical solderless wrapped connection

terminal, and the connection is held together thereafter by the elastic stresses left in the two members. A typical solderless wrapped connection is shown in Fig. 1.

For Bell System applications, a minimum of 5 turns of wire is specified when no. 22 gage wire is used, and a minimum of 6 turns is specified when no. 24 gage wire is used. The wire should be closely wound on the terminal, but turns of wire should not overlap.

Only solid copper wire has been approved for solderless wrapping. The use of stranded wire presents a number of difficulties and has not been investigated in detail.

RELIABLIITY OBJECTIVES

The general reliability objective in the development of solderless wrapped connections has been that the connections should remain mechanically secure and electrically stable during manufacture, shipment, and installation and for 40 years thereafter in telephone central office service.

The mechanical security objective cannot be defined in absolute terms, for too little is known about the magnitudes and distributions of the disturbances to which wires are subjected in service. As a comparative objective, however, solderless wrapping should not increase the occurrence of broken wires and loose connections beyond the levels that now prevail with soldered connections.

The electrical stability objective can be stated more specifically. Not more than one connection in 10,000 should exhibit resistance fluctuations greater than 0.1 ohm in service. The electric noise produced by resistance fluctuations of this magnitude is considered to be at the threshold of transmission impairment in the most critical transmission circuits now in service.

Electrical Measurements

The method used for checking the electrical stability of solderless wrapped connections has been described fully by Van Horn.[2] In essence, it consists of a resistance measurement made by the familiar voltmeter-ammeter method. The voltage drop across the connection is measured with a moving coil millivoltmeter while a direct current of 0.1 ampere flows through the connection.

The measurement of interest is the variation of resistance when the connection is disturbed mechanically. The disturbance is created by plucking the terminal, that is, by slowly deflecting the free end of the terminal a predetermined distance and then releasing it abruptly, allowing the terminal and the connection to vibrate freely. The resistance variation (ΔR) is the difference between the maximum and minimum resistance value observed during the disturbance.

Although the moving coil millivoltmeter is too sluggish to follow rapid fluctuations of resistance, the measurement is surprisingly sensitive. In a series of measurements made by an appropriate electric noise meter, while connections were subjected to vibration of the sort encountered in service, the measured noise levels consistently were lower than the levels calculated from the results of the simple ΔR measurements. It was concluded that the simple ΔR measurement would be adequate for routine development tests, and, since it could be made far more rapidly than any of the more refined measurements that had been explored, it was adopted.

ANALYSIS OF ΔR MEASUREMENTS

Before reviewing the accelerated aging tests that have been employed in the evaluation of solderless wrapped connections, it is necessary to describe the method that will be used to summarize the results. This method, a product of hindsight rather than foresight, has been used for only a short time in the solderless wrapped connection development.

A major problem in the evaluation, of course, has been to demonstrate by means of comparatively small samples that the probability of ΔR exceeding 0.1 ohm is no more than one in 10,000. The expense of testing large enough samples to determine the frequency distribution of ΔR in every case would have been prohibitive. Over a period of years, however, a moderately large number of tests were made on a few particular types of connections. The cumulative sample sizes in those cases, although still small compared with 10,000, were large enough to warrant attempts at curve fitting.

As measured by the chi-square test, the expression that seems to fit the observed distributions best is obtained by first grouping the ΔR data in cells as follows:

Cell Number x	ΔR, Ohms	Number of Connections in Cell
0	$0 \leq \Delta R \leq 0.001$	n_0
1	$0.001 < \Delta R \leq 0.01$	n_1
2	$0.01 < \Delta R \leq 0.1$	n_2
3	$0.1 < \Delta R \leq 1.0$	n_3
⋮	⋮	⋮

The arithmetic mean of the grouped distribution then is calculated as follows:

$$m = \frac{0n_0 + 1n_1 + 2n_2 + 3n_3 + \dots}{n_0 + n_1 + n_2 + n_3 + \dots}$$

$$= \frac{n_1 + 2n_2 + 3n_3 + \dots}{N} \tag{1}$$

where N is the total number of connections in the sample.

Once the mean m has been calculated, the probability of finding a connection in cell x can be expressed as

$$P_x = \frac{m^x \epsilon^{-m}}{x!} \tag{2}$$

Bearing in mind that $0! = 1$, the probabilities associated with the first few cells become

$$P_0 = \epsilon^{-m} \tag{3A}$$

$$P_1 = mP_0 \tag{3B}$$

$$P_2 = mP_1/2 \tag{3C}$$

$$P_3 = mP_2/3 \tag{3D}$$

The reader may recognize that equation 2, the general expression for P_x, is the same as the expression for the Poisson distribution. The physical interpretation, however, is different. In the Poisson distribution, P_x is the probability that x defectives will occur in a random sample of size N if m is the expected average number of defectives in a sample of that size. As a description of the ΔR distribution, however, P_x is the probability that ΔR, for a single connection chosen at random, will fall between the limits defined by the cell number x. For a random sample of N connections, then, the number of connections expected to fall in cell number x will be NP_x.

In general, the agreement between equation 2 and observed ΔR distributions has been best for the more stable types of connections, types in which high values of ΔR rarely occur and for which m is small. These, of course, are the types of connections that are desirable. For less stable types of connections, the types that would be rejected as unreliable, the agreement has been poorer. The dividing line between good agreement and poor agree-

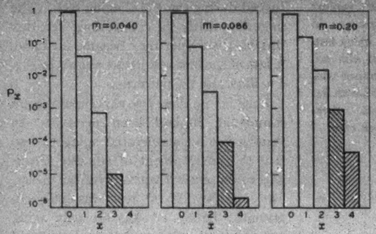

Fig. 2 (left). Examples of ΔR distribution defined by equation 2. Shading indicates cells for which ΔR exceeds 0.1 ohm

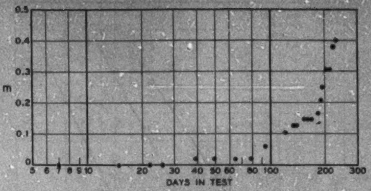

Fig. 3. Effect of 105 C accelerated aging test on solderless connections wrapped with no. 24 gage copper wire on solder-dipped twin-wire terminals of wire spring relay. Sample size 48

ment appears to be somewhere in the vicinity of $m=0.3$.

The mean m is a convenient statistic to use in summarizing the results of a group of ΔR measurements, and it will be used for that purpose in the discussion of accelerated aging tests. Qualitatively, low values of m indicate stable connections, and high values indicate unstable connections. Quantitatively, in those cases where m is less than about 0.3, m defines the observed ΔR distribution very effectively.

The distribution corresponding to $m=0.086$ (shown in Fig. 2) is of particular interest. It represents the case for which there is one chance in 10,000 that ΔR will exceed 0.1 ohm. Consequently, a value of $m=0.086$ in service is the maximum value that will satisfy the stability objective for central office use of solderless wrapped connections in the Bell System.

One more point needs to be made before proceeding to the discussion of accelerated aging tests. The variance of the distribution described by equation 2 is equal to the mean m. It follows, then, that the standard deviation is equal to the square root of m. This relationship will be used later in developing criteria for deciding whether or not connections are stable enough to be approved.

Accelerated Aging Tests

Fairly early in the development of solderless wrapped connections, it was concluded that electrical instability, if it occurred at all, would result principally from relaxation of stresses in the wire and terminal, the stresses that hold the connection together. Since that time, all aging tests employed in the evaluation of solderless wrapped connections have included elevated temperatures to accelerate the relaxation process.

The work of Mason and others[2,3] indicated that the stress in copper wire (measured with respect to its value one day after a connection was wrapped) would relax about 40% in 40 years at room temperature. To allow for some error in the room temperature prediction, and to allow for the fact that temperatures in enclosed equipments may approach 55 C (degrees centigrade) in some cases, it has been assumed that the stresses in solderless connections wrapped with copper wire may relax as much as 50% under central office conditions. That has been the degree of stress relaxation aimed at in the various accelerated aging tests.

One of the early tests consisted simply of baking the connections for 3 hours at 175 C. (Mason had shown that the stresses in connections wrapped with copper wire would relax 50% in about $2^1/_2$ hours at 175 C, and the extra half-hour was needed to bring the specimens from room temperature up to the oven temperature.) At the end of the heat treatment, the connections were cooled to room temperature and then were checked for electrical instability. The general experience was that any solderless wrapped connection which was stable before the heat treatment still would be stable after the heat treatment.

Although such results were encouraging, they were, at the same time, disconcerting. For example, some of the connections that behaved so well in the 175 C test were wrapped on terminals that scarcely could be considered good mechanical structures for supporting stresses over long periods. The twin-wire terminal of the wire-spring relay, in particular, fell in the questionable category. At that time it consisted simply of two parallel nickel-silver wires which were bonded together by dipping them in soft solder and which then were serrated. The parallel wires by themselves did not have sufficient torsional stiffness to support the stresses that are required to hold a solderless wrapped connection together. And soft solder, because of its cold flow properties, is a notoriously poor material for supporting stresses. It was doubtful that the soft solder, at room temperature, could maintain the stresses long enough at levels high enough for solid-state diffusion to occur. Since 175 C was not far below the softening temperature of the solder, there was at least a suspicion that something akin to a soldered joint had been produced in the accelerated aging test.

There were questions, also, about the metallurgical behavior of the copper wire at the elevated temperature. It was known, for example, that recrystallization is more likely to occur in copper at 175 C than at lower temperatures.

In short, it was suspected that a temperature as high as 175 C might do more than accelerate the aging process: it might alter the physical nature of the aging process itself. If this were so, then the 175 C test might give a false picture of the aging that would occur in actual service.

105 C AGING TEST

It was decided therefore that some exploratory aging tests should be run at a substantially lower temperature. For several reasons, a temperature of 105 C was chosen. It was well below the softening temperature of tin-lead solders, it was low enough so that there should be little likelihood of recrystallization occurring in the copper wire, yet it was high enough to produce the desired stress relaxation in a few months. Mason's work had indicated that the stresses in the wrapped connections would relax 50% in about 150 days at 105 C, so the test period was set at 150 days, or about 5 months.

As compared with the desired service life of 40 years, the 3-hour 175 C test represented a 100,000 to 1 acceleration of the stress relaxation process. Since the 5-month 105 C test would represent an acceleration of only 100 to 1, it was expected to be a far more realistic aging test.

Five months is a long time, however, to wait for test results. It was decided

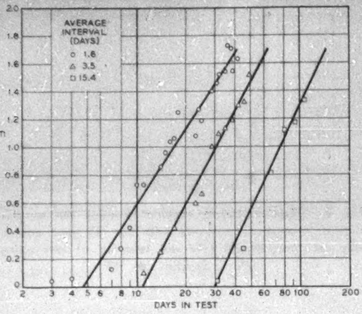

Fig. 4. Effects of varying frequency of disturbance in 105 C accelerated aging test. Connections wrapped with no. 24 gage tinned copper wire on 0.010- by 0.062-inch flat nickel-silver terminals. Sample size 48 in each case

therefore that the test connections should be measured periodically during the aging test so that any instability would be detected as soon as it occurred. It is important to note that this decision introduced two more changes in the accelerated aging test: 1. it subjected the connections to temperature cycling, for they were removed from the oven and allowed to cool whenever they were measured, and 2. it subjected the connections to mechanical disturbances while they were being aged, for the terminals were plucked whenever resistance variations were measured.

The first connections subjected to the 105 C aging test were wrapped on the solder-dipped twin-wire terminals that were described earlier. Connections of that type had survived the 175 C test without showing any evidence of instability. In the 105 C test, however, they soon began to exhibit measurable resistance fluctuations, and they grew more and more unstable as the test continued. The history of that first group of connections is plotted in terms of the statistic *m* in Fig. 3. It was evident that the 105 C aging test with periodic cycling and measurement was more severe than the undisturbed 175 C test.

Subsequently an experiment was performed to compare the relative effects of temperature, temperature cycling, and mechanical disturbance. One group of connections was aged at 105 C, was cooled to room temperature once each week, and was measured (plucked) while at room temperature on alternate weeks. At the end of 150 days, the value of *m* for that group was 2.1.

A second group of similar connections was aged at 105 C, was cooled to room temperature once each week, but was not disturbed by measurements. After 150 days, *m* was 0.2.

A third group was aged continuously at 105 C without either temperature cycling or mechanical disturbance. After 150 days, *m* was 0.04.

A fourth group was maintained continuously at room temperature but was measured every two weeks. After 150 days, *m* was 0.02.

Three important inferences were drawn from the results of this experiment:

1. Although solid-state diffusion may occur during undisturbed aging of solderless wrapped connections, thus tending to offset the detrimental effects of stress relaxation, repeated mechanical disturbances during the aging process can impede diffusion and can lead to unstable connections.

2. Since connections may be disturbed from time to time in service, accelerated aging tests should include periodic mechanical disturbances.

3. Temperature cycling alone can produce a form of mechanical disturbance if the temperature coefficients of expansion of wire and terminal are not equal.

Another related experiment was performed to study the effects of the frequency with which connections are disturbed during the 105 C aging test. The more frequently the connections were disturbed, the sooner they became unstable. A few of the test results are shown in Fig. 4 to illustrate the pattern.

Long before these two experiments were completed, it had been necessary to standardize an accelerated aging test so that the development of suitable terminals could proceed without further delay. The 150-day 105 C test was adopted, primarily because it was the only aging test up to that time that had revealed highly significant differences among various types of connections, differences that usually were consistent with qualitative analyses of the various mechanical structures. The connections were cooled to room temperature once each week, and their resistance variations were measured at room temperature every other week. Each connection was plucked two or three times during the ΔR measurement. Eventually a plucking amplitude of 1/32 inch was standardized.

A standard procedure for the preparation of test specimens also evolved gradually. It has become the usual practice now, in preparing each group of test connections, to use two wrapping bits (one that wraps more tightly than the average bit, and one that wraps less tightly), two wrapping tools (one power-driven and the other manually operated), two grades of wire (one comparatively hard and the other comparatively soft), and two operators. All 16 combinations of the 4 parameters are included at least twice in each test nowadays.

RESULTS OF 105 C ACCELERATED AGING TEST

Altogether, more than 11,000 solderless wrapped connections have been subjected

to the 105 C accelerated aging test. Most of the tests have been aimed at the problem of finding terminal configurations which would yield reliable connections and which, at the same time, could be manufactured economically. The results of a number of those tests are summarized in Table I along with the results of a screening test that is described in a later section.

Fig. 5 shows the results that were obtained with no. 24 gage tinned copper wire wrapped on terminals punched from several widely used thicknesses of nickel-silver stock. The performance of the thinner terminals was considered to be unsatisfactory. Various types of longitudinal embossing were investigated to find means for improving the thin terminals, and the form shown in Fig. 6 finally was standardized. Although this form is not necessarily optimum, it is a convenient form to manufacture; and it has behaved well in the accelerated aging test, as shown in Table I.

The early single-wire terminal of the wire-spring relay was formed from a round wire by flattening, serrating on one side, and solder dipping. Its performance was unsatisfactory, but it was improved simply by omitting the solder. Its present form is shown in Fig. 7.

The twin-wire terminal of the wire-spring relay was more of a problem. Many designs were conceived and investigated, but most of the designs that showed promise from the solderless wrapping standpoint were objectionable from the manufacturing standpoint. In the end, a compromise design was adopted. The twin wires are twisted tightly together, then they are coined in a closed die which has a trapezoidal cross section. The resulting terminal is shown in Fig. 8.

Although most of the 105 C tests have been made with no. 24 gage wire, a number of tests have been made also with no. 22 gage wire. As shown in Table I, the results indicate that no. 22 gage connection the heavier terminals are as stable as no. 24 gage connections but that no. 22 gage connections on the lighter terminals are inferior.

The aging tests of no. 26 gage connections are not completed yet. The preliminary results indicate, however, that no. 26 gage connections, even when wrapped with as many as 9 turns of wire, are less stable than 6-turn no. 24 gage connections on the same types of terminals.

For certain types of wiring in the Bell System, it has been standard practice to use untinned copper wire. Solderless connections wrapped with untinned wire, however, tend to deteriorate sooner than connections wrapped with tinned wire. Fig. 9 illustrates results obtained with untinned wire.

The data that have been presented so far should be sufficient to provide a bird's-eye view of the results that have been obtained in the 105 C aging test. Other alleys and byways have been explored, but the picture would not be sharpened perceptibly by presenting more details. It is more pertinent at this point to consider what use can be made of the test results.

Criteron for Acceptance (105 C Aging Test)

The purpose of the accelerated aging test, of course, is to distinguish between

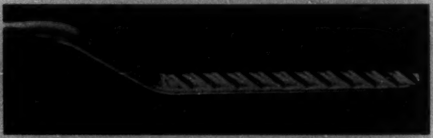

Fig. 7. Single-wire terminal of wire-spring relay

Fig. 8. Twin-wire terminal of wire-spring relay

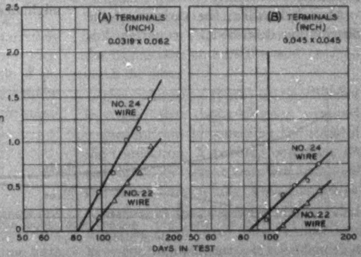

Fig. 9. Effect of 105 C accelerated aging test on connections wrapped with untinned copper wire on electrotinned brass terminals. Sample size 32 in each case

those types of solderless wrapped connections which are likely to satisfy the 40-year stability objective in service and those types which are not likely to satisfy the objective. The test results supply a reasonably clear picture of the relative instability of the several types of connections, but this by itself is not enough. Somewhere on the instability scale, the development engineer eventually must draw a line and say, at least to himself, "I will approve the use of types of connections that fall below this line; I will not approve types that fall above it." In other words, he must establish a criterion for acceptance.

The criterion for acceptance has not remained static as the development of solderless wrapped connections progressed. Instead, it has been revised several times as the aging test evolved and as the information obtained from aging tests expanded. Its present form has considerably more meaning and is more convenient to use than some of the earlier forms.

The criterion for acceptance is based upon two premises: 1. that the 105 C accelerated aging test does, in fact, produce at least as much instability as 40 years of central office service will produce, and 2. that equation 2 is an adequate description of the ΔR distribution. Although final confirmation will not be available until about 1990, evidence that these premises are valid is increasing year after year.

It was stated previously that the value of m should not exceed 0.086 in service if the resistance variation of not more than one connection in 10,000 is to exceed 0.1 ohm. If the 105 C test is an adequate simulation of service conditions, then those types of connections which have values of m below 0.086 in the 105 C test should be acceptable. This would be the criterion for acceptance if very large samples were tested. Where small samples are tested, however, it is prudent to make allowance for sampling errors.

As stated earlier, the variance of the distribution described by equation 2 is equal to m. Consequently, the standard deviation of the distribution is equal to the square root of m. If a large number of samples of size N are drawn from a population whose true mean is m', then roughly 5% of the sample means can be expected to fall below the value

$$m_{0.05} = m' - 1.645\sqrt{m'/N} \qquad (4)$$

A reasonable acceptance level, then, is

$$\begin{aligned} m_{0.05} &= 0.086 - 1.645\sqrt{0.086/N} \\ &= 0.086 - 0.482/\sqrt{N} \qquad (5) \end{aligned}$$

In other words, the stability of the connections will be considered acceptable if the mean m of a sample of N connections is less than the value of $m_{0.05}$ given by equation 5. The acceptance level is plotted as a function of N in Fig. 10.

As an aid to decision making, it also is possible to set up a criterion for rejection. If a large number of samples of size N are drawn from a population whose true mean is m', then roughly 95% of the sample means can be expected to fall below the value

$$m_{0.95} = m' + 1.645\sqrt{m'/N} \qquad (6)$$

A reasonable rejection level for the case $m' = 0.086$, then, is

$$m_{0.95} = 0.086 + 0.482/\sqrt{N} \qquad (7)$$

In other words, the stability of the connections will be considered unacceptable if the mean m of a sample of N connections exceeds the value of $m_{0.95}$ given by equation 7. Further testing of that particular type of connection is not very likely to be profitable, so it might as well be rejected.

Establishing a rejection limit that does not coincide with the acceptance limit provides a zone of uncertainty in which the connections are neither clearly acceptable nor clearly unacceptable. It recognizes the possibility that further testing of a marginal type of connection might demonstrate that the type is acceptable. If the value of being able to approve that type of connection outweighs the cost of further testing, then it may be worth while to continue.

On the average, the acceptance criterion of equation 5 is conservative. Not only does it provide margin for moderate sampling errors, but it also provides some margin, on the average, for an error in the basic premise that the 105 C test adequately simulates aging in service.

At the same time, the form of equation 5 is helpful to the experimenter, for it tells him the minimum sample size that can be used as the basis for acceptance. By setting $m_{0.05}$ equal to zero in equation 5, the corresponding minimum sample size is found to be 32. If he tests 32 connections and m turns out to be zero, he is entitled to approve the connections without further testing. With a smaller sample, he would not be entitled to approve them even though m turned out to be zero.

From a practical standpoint, it is prudent to test a larger sample when approval is needed in the shortest possible time. If ΔR for even a single connection exceeds 0.001 ohm in a sample of 32, then the connections cannot be approved, so the test has to be expanded, and the final decision is delayed. A practical compromise is to test a sample large enough so that four connections could exceed 0.001 ohm slightly without causing m to exceed $m_{0.05}$. If $x = 1$ for the four connections, then $m = 4/N$ and, from equation 5, the corresponding sample size is 104.

175 C Screening Test

Although the 105 C test appears to be quite effective in distinguishing between stable connections and unstable connections, its slowness is a practical disadvantage. In cases where a number of alternate terminal designs are being considered, for example, and where it is desirable to concentrate development effort on a few of the most promising alternates, the 5-month waiting period can be

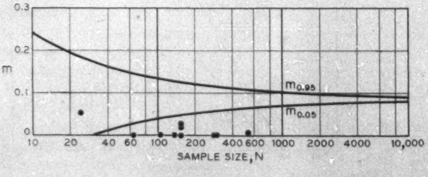

Fig. 10. Criteria for acceptance and rejection in 105 C accelerated aging test. Points are results of 105 C tests on approved types of solderless wrapped connections

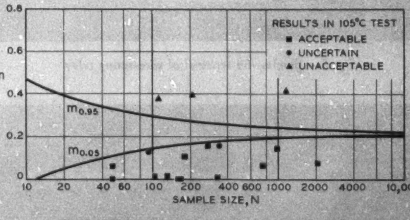

Fig. 11. Criteria for acceptance and rejection in 175 C screening test. Points are results of 175 C tests, but symbols indicate how similar connections behaved in 105 C tests

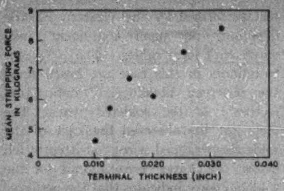

Fig. 12. Effect of terminal thickness on stripping force. Connections wrapped with no. 24 gage tinned copper wire on flat nickel-silver terminals 0.062-inch wide. Sample size 100

extremely inconvenient. There is need, therefore, for a quick screening test that will serve to identify those types of connections that are likely to pass the 105 C aging test.

Early experience with the 105 C test suggested that addition of mechanical disturbances to the original 3-hour undisturbed 175 C test might make it capable of detecting potentially unstable connections. Within limits, this proved to be so.

In the screening test that eventually was standardized, the solderless wrapped connections are baked in an oven for 3 hours at 175 C. The 3-hour period includes the warming up period of the oven and fixtures, which amounts to about one-half hour with the equipment that has been used. During the entire 3-hour period, each terminal is plucked automatically once per minute. The plucking mechanism deflects the free end of each terminal 1/16 inch, then releases it abruptly, allowing the terminal and lead wire to vibrate freely. The opposite end of the terminal is supported rigidly, of course, and the unsupported length (on which the connection is wrapped) is 19/32 inch.

At the end of the 175 C heat treatment, the connection is cooled to room temperature, and its resistance variation is measured as described previously except that 1. the terminal is plucked only once during the measurement instead of two or three times, and 2. it is plucked 1/16 inch instead of 1/32 inch.

In ordinary cases, where there is no soft solder in the connection, the correlation between the results of this test and the results of the 105 C test has been reasonably good. The principal discrepancy is that the 175 C test is not as sensitive as the 105 C test; that is, the spread between stable and unstable connections tends to be smaller in the 175 C test than in the 105 C test. This can be seen in Table I.

Despite its limitations, the 175 C screening test has been extremely useful in conserving testing effort and in speeding up various phases of the development program. Altogether, more than 16,000 solderless wrapped connections have been subjected to the 175 C test. On a few occasions, final approval of particular types of connections has been based upon results of the 175 C test, although the usual practice is to withhold final approval until the 105 C test is completed.

CRITERION FOR ACCEPTANCE (175 C SCREENING TEST)

Empirically, it is possible to define acceptance and rejection limits for the 175 C test that will correspond roughly to the limits for the 105 C test. Although such limits actually have not been used in the past, it appears that limits based upon $m'=0.22$ for the 175 C test would have led to essentially the same decisions that were made on the basis of 105 C test results. For $m'=0.22$, the limits for the 175 C test would be

$$m_{0.05}=0.22-0.77/\sqrt{N} \qquad (8)$$

and

$$m_{0.95}=0.22+0.77/\sqrt{N} \qquad (9)$$

These limits are shown in Fig. 11, along with observed values for various types of connections that have been subjected to both the 175 C and the 105 C tests. The symbols used for the values observed in the 175 C test indicate how similar types of connections fared in the 105 C test.

As indicated previously, the limits for the 175 C test can serve as guides for making decisions. If m for a particular type of connection is less than $m_{0.05}$, it probably is worth while to make tests at 105 C. If m is greater than $m_{0.95}$, it probably is not worth while. If m falls between $m_{0.05}$ and $m_{0.95}$, the decision will have to be based upon additional considerations.

The sample size for which $m_{0.05}=0$ is about 13. The sample size for which $m_{0.05}=4/N$ is about 41. A sample of 13, then, is the smallest sample that should be tested, and 41 is a more realistic minimum.

Mechanical Tests

Certain standard mechanical tests are made regularly to qualify wrapping bits for use in production, and the same tests have been made to qualify the bits used in the evaluation studies. Sample connections are wrapped on specified types of terminals, then two different types of tests are made on the sample connections. In the first test, the force required to strip the connection off of the terminal is measured. It is required that this stripping force be at least 3,000 grams and that the median for any subgroup of 5 connections be at least 4,200 grams. The purpose of this test is to provide assurance that the bit is capable of wrapping tight connections.

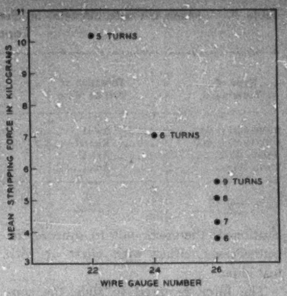

Fig. 13. Effect of wire size on stripping force. Connections wrapped with tinned copper wire on 0.0319 by 0.062-inch nickel-silver terminals. Sample size 50–175

In the second test, the wire is unwrapped from the terminal, the unwrapping force being applied to the wire at least one-half inch from the terminal without restraining the wire from twisting or bending back upon itself. It is required that the connection be capable of being unwrapped in this fashion without the wire breaking. The purpose of this test is to provide assurance that the bit does not wrap too tightly—so tightly that the wire would be weakened excessively.

Assuming that the connections have been wrapped with qualified bits, it is of interest to consider what might happen to them subsequently in service. In general, this reduces to a consideration of mechanical treatments that would tend to loosen the connection and that would tend to break the wire.

The principal types of mechanical treatment that could loosen a wrapped connection are 1. squeezing the sides of the connection, 2. pushing or pulling on the body of the connection, and, of course, 3. unwrapping the connection.

Although the squeezing forces that would be required to loosen connections have not been measured, it is evident that enough force could be exerted with a pair of pliers to damage a connection. Wiremen and maintenance men have been

Table II. Mean Ultimate Strength, in Grams, of Connections Made with No. 24 Gage Copper Wire

Type of Terminal	Direction of Pull on Wire	Solderless Wrapped Connections, 6 Turns	Wrapped and Soldered Connections, 1¼–2 Turns
0.0319 by 0.062	Axial	2,330	3,030
0.0319 by 0.062	Radial	4,814	5,205
Single Wire	Axial	4,450	4,444
Twin Wire	Axial	4,527	4,512

cautioned, therefore, not to squeeze the connections, either with pliers or with test clips.

The force required to slide the connection along the terminal ordinarily is well above the minimum requirement of 3,000 grams, ranging up to more than 10,000 grams in some cases. In general, the heavier terminals tend to give higher stripping forces than the lighter terminals, and the heavier gages of wire tend to give higher values than the lighter gages. Figs. 12 and 13 illustrate the relationships.

Ordinarily there is little risk that a connection will be unwrapped in normal wiring or maintenance operations—unless, of course, the wire is unwrapped deliberately to remove the connection. It is possible, nevertheless, to unwind a connection by pulling steadily on the lead wire in the direction parallel to, and in line with, the terminal axis. On the average, a force of about 825 grams is sufficient to unwrap one-half turn of a no. 24 gage connection on a 0.0319- by 0.062-inch terminal, and a force of about 2,300 grams will unwrap one full turn. The standard deviations are about 15% of these values.

The principal types of mechanical treatment that are liable to break wires in service are 1. tension alone, 2. repeated bending alone, and 3. repeated bending combined with tension. A number of tests have been made to compare the effects of these treatments on wires connected to terminals by solderless wrapping with the effects on wires connected by soldering.

The results of a few tensile tests are summarized in Table II. When the wire was pulled radially (perpendicular to the terminal axis), almost the full breaking strength of the wire was realized with the soldered connections. The breaking strength with the solderless wrapped connections was about 8% lower, however, because the wire was indented where it had been wrapped around the corners of the rectangular terminal.

It is interesting to note that, even with soldered connections, the full breaking strength of the wire was not realized when the wire was pulled axially. The soldered joint was broken in stages, and the wire was completely unwrapped from the terminal in most cases before the force reached the breaking strength of the wire. With the flat terminals, the ultimate strength of the solderless wrapped connections was significantly lower than that of the soldered connections. With the wire spring relay terminals, on the other hand, the differences between the solderless wrapped and the soldered connections were trivial. The serrations of the single wire terminal and the irregularities of the twisted and coined twin wire terminal were as effective as soldering in locking the wrapped wire in place.

The effects of repeated bending without tension are illustrated in Fig. 14. The test was performed by bending the wire back and forth through the angles indicated until the wire broke. The bending moments were large enough to exceed the elastic limit of the copper wire. In Fig. 14, conventional $\pm 3\sigma$ control limits (or confidence limits) are shown with each plotted point as a simple, graphic way of indicating that the performance of the solderless wrapped connections was significantly better, on the average, than that of the soldered connections.

Vibration tests, of course, provide another method for measuring the effects of repeated bending without tension. Fig. 15 shows the results of a vibration test performed by the Western Electric Company on small equipment units wired with local cables. The $\pm 3\sigma$ control limits in this case are based upon the observed breakage ("fraction defective") of the soldered wires. The fact that the observed breakage of the solderless wrapped wires consistently fell below the lower control limit for the soldered wires indicates that the performance of the solderless wrapped wires was superior on the average.

The effects of repeated bending combined with tension are shown in Fig. 16. In this test, the wire was kept under tension continuously while it was bent from its starting position perpendicular to the terminal axis to a second position parallel to the terminal axis and then back to its starting position. This cycle was repeated, always in the same direction from the starting position, until the wire broke. In Fig. 16, the $\pm 3\sigma$ control limits indicate again that the performance of the solderless wrapped wires was better, on the average, than the performance of the soldered wires.

From the results of tests such as those which have been described, it has been concluded that the solderless wrapped connection satisfies the mechanical security objectives in part, but not completely. It is more vulnerable to loosening by axial pull on the wire than is the soldered connection, so this limitation should be recognized in authorizing applications of solderless wrapping. In its ability to withstand vibration and repeated bending of the lead wire, however, the solderless wrapped connection appears to be fully as good as, and probably better than, the soldered connection.

Approved Combinations of Terminals and Wire

Present approvals of specific combinations of terminals and wire are based

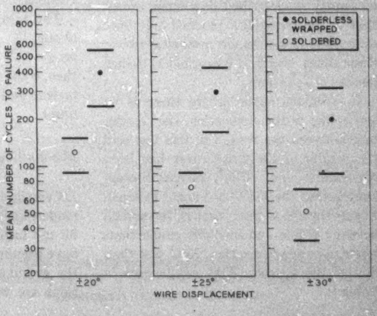

Fig. 14 (right). Effects of repeated bending without tension. Connections made with no. 24 gage tinned copper wire on single-wire terminals of wire spring relay. Sample size 16

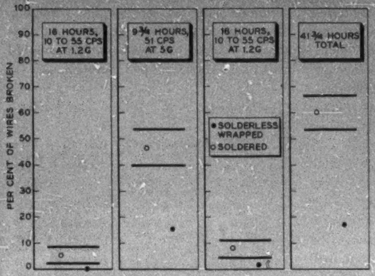

Fig. 15. Results of vibration test on small equipment unit wired with local cable. Sample size 550 for each type of connection

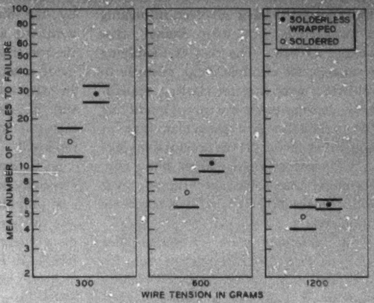

Fig. 16 (right). Effects of repeated bending with wire under tension. Connections made with no. 24 gage wire on single-wire terminals of wire-spring relay. Sample size 25 in each case

very largely upon the results of the accelerated aging tests that have been described, upon the ability of the manufacturer to manufacture the terminals economically, and upon a limiting dimension of a wrapping bit that is used widely.

The limiting dimension is the minimum diameter of the terminal hole in the bit used for wrapping no. 24 gage wire. In order to be sure that no. 24 gage wire can be wrapped on any approved terminal, the maximum dimensions of the cross section are limited so that the terminal will pass through a circular opening 0.073 inch in diameter.

Solderless wrapping with no. 22 gage tinned copper wire is approved on terminals of rectangular cross section whose nominal thickness is at least 0.030 inch and whose minimum diagonal exceeds 0.061 inch.

Solderless wrapping with no. 24 gage tinned copper wire is approved on 1. terminals of rectangular cross section whose nominal thickness is at least 0.025 inch and whose minimum diagonal exceeds 0.059 inch, 2. embossed terminals of the form shown in Fig. 6 punched and formed from flat stock whose nominal thickness is at least 0.010 but less than 0.025 inch, and 3. the wire-spring relay terminals shown in Figs. 7 and 8.

Approved terminal materials include nickel silver, brass, phosphor bronze, and silicon copper. The best terminal materials for solderless wrapping have a high modulus of elasticity, a low rate of stress relaxation, and a temperature coefficient of expansion near that of the wire.

In general, a copper flash plus an electrotinned finish is required on brass, phosphor bronze, and silicon-copper terminals, or they may be punched from either tin-coated or solder-coated stock. No finish is required on nickel-silver terminals, although any of the foregoing finishes is permissible and is specified in some cases to facilitate soldering. Solder dipping is not approved because of the risk of obtaining abnormally thick coatings from time to time and the undesirable effect that this could have upon the stability of connections wrapped on such terminals.

The use of untinned copper wire has been approved only in cases where the required service life of the connections is substantially less than 40 years. Furthermore, such approvals are limited to the heavy terminals which are approved for use with no. 22 gage wire.

There have been exceptions to some of the standards described in the preceding paragraphs. Solderless wrapping on solder dipped terminals and on thin, flat terminals was approved on a limited basis early in the development program. Those connections, however, are in circuits where trouble, if it should occur, would be detected automatically, could be located quickly, and could be corrected easily by soldering the defective connection. For future production, those terminals are being brought into agreement with present standards.

Performance in Service

The first field trial of solderless wrapped connections was installed in 1950, and limited use of solderless wrapping in regular manufacture began a few years later. During the period 1950–1958, the service performance of solderless wrapped connections appears to have been highly satisfactory.

A 2-year survey of 411,000 solderless wrapped connections in five central offices showed a lower wire breakage rate than would have been expected with soldered connections, and the difference was great enough to be considered statistically significant.

There has been no report of solderless connections being pulled off of terminals in service or of being partially unwrapped, and inspection of about 20,000 connections in two central offices revealed no sign of partial unwrapping.

The resistance variations of 135 connections were measured after 2 years in service, and 160 more were measured after $3^1/_2$ years of service. The highest value of ΔR observed was 0.0004 ohm, so the value of m for the 295 connections still was zero.

Conclusions

The laboratory studies and field experience to date have provided considerable assurance that properly designed and properly made solderless wrapped connections will perform satisfactorily for 40 years in central office service. The use of solderless wrapping is being expanded, therefore, in the Bell System. Suitable terminals are being provided now on many types of telephone apparatus. Design changes have been authorized to provide suitable terminals on a number of additional types of apparatus, although the changes have not been introduced yet in manufacture. And design changes to provide suitable terminals on still other types of apparatus are being studied.

Several hundred million solderless connections are being wrapped each year in the Bell System now. The number will grow, but it is difficult to predict what the saturation level will be. Inevitably, the solderless wrapped connection is in competition with soldered connections, clinched connections, welded connections, and all the other types. In the end, the choice of connections for any particular application is likely to be an economic choice, based not only upon the cost of the labor involved in making a connection, but upon many other factors as well. The cost of modifying terminals, for example, is an obstacle to solderless wrapping on existing apparatus. In some cases, the cost of modifying the terminals of a particular type of apparatus outweighs the potential savings of solderless wrapping. It is not likely, therefore, that solderless wrapping ever will displace other types of connections completely.

The present program for central office equipment in the Bell System calls for modification of the terminals of existing types of apparatus in those cases where the preparation expense clearly is outweighed by the direct savings from solderless wrapping and the indirect savings from the use of plastic insulated wire, which is made practicable by solderless wrapping. In other cases, modification of terminals will be deferred until present manufacturing tools wear out and have to be replaced.

In designing new types of apparatus, especially switching apparatus, the trend is to provide terminals suitable for solderless wrapping at the start. Furthermore, every effort is made to arrange the terminals in modular arrays that will facilitate automatic wiring by machines. These two steps are opening a door to economical use of automatic wiring in manufacture. It seems quite probable, therefore, that telephone switching systems of tomorrow will be well populated with solderless wrapped connections.

Telex in New York

PHILIP R. EASTERLIN
MEMBER AIEE

AN AUTOMATIC dial teleprinter exchange service was placed in operation in May 1958, through which subscribers in New York City may obtain direct teleprinter connections, in a matter of seconds, to over 1,200 subscribers throughout Canada.

The new service, internationally known as "Telex," incorporates the characteristic automatic answer-back feature which confirms that the proper dial connection has been made and that transmission, even to unattended stations, is being correctly recorded on the distant teleprinter. The same subscriber equipment also can be used to connect to the land-line and cable tie-line sections for sending and receiving public message traffic.

The Telex Exchange at Western Union is linked by a number of carrier telegraph channels to the Montreal Exchange of the Canadian Telex network. The Canadian Telex service, comprising over 100,000 miles of telegraph trunk facilities, was placed in operation in July 1957 jointly by the Canadian Pacific and Canadian National Telegraph Companies, and its operation has been presented in an unpublished paper by Colombo.

Subscriber Set

In New York, the Telex subscriber set consists of a console-mounted type *15* teleprinter and an associated remote control (dial) unit shown in Fig. 1. A call is made simply by depressing a start button, dialing a five or six-digit subscriber number and the connection is made immediately after the last digit has been dialed. The fact that the connection has been made is indicated by the teleprinter motor starting and an operate lamp lighting. The connection can be terminated from either end by depressing a stop button which turns the equipment off. If the called subscriber is already engaged, a busy signal is returned which cuts the calling subscriber's equipment on for about one second, and then off again.

ANSWER-BACK FEATURE

The teleprinter keyboard in the subscriber set is equipped with an answer-back unit, a close-up of which is shown in Fig. 2. This device is a cylindrical drum associated with the keyboard which can be coded to transmit an answer-back sequence of 19 characters, 14 of which can be used to identify the

subscriber's name and city as listed in the Telex directory. The unit is remotely actuated by the WHO ARE YOU signal (FIGS. D) sent from the distant end, or it can be triggered locally by depressing an associated HERE IS key.

In normal operation, the calling subscriber initiates the exchange of answer-back sequences after a dial connection is established by transmitting the WHO ARE YOU signal, receiving the answer-back from the distant teleprinter and then depressing the HERE IS key to identify himself to the called subscriber. An exchange of answer-backs also may be initiated at any time during transmission to verify continuity in reception or as an over-all acknowledgment just prior to terminating a call. The answer-back, along with a paper-out protective circuit which prevents a connection being made to a subscriber's teleprinter having low paper, provides a high degree of reliability for Telex connections to unattended subscriber stations.

Subscriber Set with Local Tape Function

For Telex subscribers who require the additional operating facility of preparing, transmitting, or receiving on a 5-channel perforated tape, a special type of subscriber set is provided. This set, as shown in Fig. 3, is equipped with a Siemens model *100* page printer which has a built-in reperforator and transmitter-distributor attachment. A special type *L* remote-control unit is provided which allows the printer equipment to be used in an "off-line" manner for the advance preparation of tape. In the event of an incoming Telex call, the subscriber set is automatically switched "on-line" after a warning signal. Specifically, the set provides the following operation:

1. Off-line operation when idle, enabling the keyboard to be used for preparation of tape from reperforator attachment, along with a printed monitor copy.
2. After a connection is established, transmission may be from either the keyboard or by tape fed through the transmitter-distributor. Outbound, as well as inbound, transmission is again recorded on the page printer and the reperforator attachment may be used simultaneously to produce another tape.

The page printer used in this set also contains a 2-color ribbon feature which automatically prints the outgoing transmission from the keyboard and the incoming transmission in different colors. This is very useful when a 2-way Telex

Canadian Telex Network

The layout of the Canadian Telex network and the interconnection to the New York Telex Exchange is shown in Fig. 4. The network is divided into three areas, centralized around a junction exchange in each area. These are area *01*, Montreal, area *02*, Toronto, and area *03*, Winnipeg. Other exchanges such as New York (*015*) are designated as district exchanges and are assigned three digits, the first two represent the junction area and the third digit denotes the district exchange within that area. The subexchange, which is usually in a nearby city to the district exchange, functions as an integral part of its respective district exchange by the assignment of a different fourth digit. For example, *036* designates the Vancouver, B. C., district exchange and *0366* switches a call through to a subexchange located at Victoria, B. C.

Local subscribers connected to the various junction and district exchanges are assigned either 5- or 6-digit dial numbers such as *03-564* for a Winnipeg subscriber or *015-222* for a New York subscriber. The digits on the right side of the hyphen denote the local number which is dialed to reach another subscriber who is terminated in the same junction or district exchange as the calling subscriber. For long-distance connections, calls to subscribers terminated by other junction or district exchanges, the complete number of digits, i. e., *03564*, must be dialed.

While the Telex exchange equipment used in Canada and New York City employs the direct dial or step-by-step principle and completes the connection as soon as the last digit has been dialed, it does impose certain restrictions on the routing of calls over trunk circuits. For example, the system does not normally employ registers for storing the dial digits and selecting alternate routes for calls when all trunks are busy or faulted. Therefore each long-distance call between two exchanges, excluding the subexchange, is given a predetermined route through one or more junction exchanges. For example, a New York call to Vancouver is routed New York–Montreal – Winnipeg – Vancouver and could not be passed through an additional Telex exchange such as Montreal–Toronto–Winnipeg, etc. Also, calls between local subscribers in subexchanges must be handled through the respective district exchange.

How a Telex Connection is Established

Before describing the technical functions of the switching equipment in the Telex exchange, a description will be given of the various steps which take place in establishing a long-distance Telex connection. A typical call would be where a New York subscriber dials *036-292* to reach a subscriber in Vancouver, B. C. The connection through the group-selector switches and repeater equipment in the various Telex exchanges for such a call is illustrated in simplified form in Fig. 5.

When not in use, the teleprinter motor in the subscriber set is turned off and the dial on the remote-control unit is locked. To initiate a call, the New York subscriber depresses a start button which causes the subscriber's preselector switch in the Telex exchange to seize an idle group-selector switch. Almost instantly, the exchange equipment returns a "go ahead dial" signal to the subscriber, unlocking the dial and bringing up a white visual indicator located in the remote-control unit.

The subscriber dials *036292*. While these digits are being dialed, the circuit is progressively built up through the various exchanges to Vancouver. For example, *0* causes the first group-selector switch in the New York Exchange to select a trunk to Montreal; *3* actuates the second group-selector switch in the Montreal Exchange to route the call to Winnipeg, and *6* extends the circuit in a similar manner from Winnipeg to Vancouver. The last three digits, *292*, are utilized in the Vancouver exchange in order to set the group selector and final selector switches to the respective subscriber.

Upon completion of the connection, requiring about 7 or 8 seconds, the teleprinter motor and a red operate lamp on the Vancouver subscriber set are turned on. As this occurs, a free-line signal is returned to the New York subscriber, also turning on the teleprinter motor and operate lamp to indicate that a connection has been established.

At this time an exchange of answer-back codes is initiated by the calling (New York) subscriber to insure that the proper automatic connection has been made and that the called (Vancouver) subscriber's teleprinter is functioning properly. Following is a typical oper-

ating sequence which shows how the answer-back feature is used at the beginning and end of a Telex connection. Shown in parentheses is the control character which triggers the distant subscriber's answer-back unit and the symbols for the teleprinter non-printing functions, i.e., ← carriage return, ≡ line feed, ↑ figure shift, ↓ unshift.

Description of Operating Sequence	Characters Received by Both Teleprinters
WHO ARE YOU (Sent by calling subscriber)	(↑ D)

WHO ARE YOU (Sent by calling subscriber prior to disconnecting)	(↑ D)
ACKNOWLEDGMENT (Sent automatically by called subscriber)	(←≡↓) SCOTIA BANK VCR (←≡)

Without respect to the originator of a Telex call, the subscriber at either end of the circuit may terminate the connection at any time by depressing the stop key on the remote-control unit. When this occurs, the trunk circuits through the several exchanges are released sequentially, beginning at the exchange of the originating or calling subscriber. This turns off the teleprinter motor and operate lamp on both subscriber sets, making them available for initiating or receiving other connections.

BUSY SIGNAL

After dialing a subscriber who is already engaged in a connection, a busy signal will be returned which momentarily turns on and off the teleprinter motor and operate lamp of the calling subscriber and relocks the dial. Also a subscriber may receive a busy signal before completing the dialing sequence when trunk circuits are busy or faulted between two exchanges. By dialing slower than normal, it is possible to identify the blocked trunk section. For example, if a busy signal is returned after the first three digits *036* have been dialed, it would indicate a shortage of trunk facilities between Winnipeg and Vancouver.

SUBSCRIBER SET OUT OF SERVICE

If a subscriber is dialed whose equipment or connection to the exchange is faulted, or where the paper roll is too low and needs replacing, neither a busy (which could be misleading) or a free-line signal is returned and therefore the subscriber set receives no response to the dial sequence. In such cases the calling subscriber is requested to depress the stop key, which cancels the call and recycles the dial unit, enabling the subscriber to re-dial and report the difficulty to supervisory personnel. If not cancelled in this manner, the trunk circuits involved in such a call are automatically released after a short period of time.

Public Messages Over Telex

The exchange equipment is arranged so that Telex subscribers can make free calls to the land-line or cable tie-line sections to send or receive public message traffic. As such connections are established, the subscriber or the telegraph company initiates an exchange of answer-back codes by following the regular Telex operating procedure. This speeds up the movement of message traffic by eliminating the delay in obtaining acknowledgments.

By dialing *1* or *3*, respectively, the New York subscribers are automatically connected to one of a group of page-receiving-only positions in the land-line tie-line section at New York, or to similar positions in the cable office. The receiving-only teleprinters are coded with the WHO ARE YOU signal following the Western Union Telegraph Company answer-back sequence. Therefore, as a subscriber calls in and obtains the Western Union answer-back, the subscriber's answer-back unit is also triggered automatically to identify the calling subscriber.

Messages or cablegrams destined for the local Telex subscribers are handled from a group of sending-only positions in the tie-line sections of the two offices. These positions are also equipped with a remote-control dial-box unit and the operator simply dials the subscriber's number, obtains an answer-back before and after transmission of each message series and then disconnects.

Information Center

An Information Center is located in the land-line tie-line section which New York subscribers can reach by dialing *9*. This Center communicates with other information centers in the Canadian exchanges to provide subscribers with current additions or changes in the Telex directory and to exercise general supervisory control over Telex network operations. Canadian exchanges may connect to the New York Information Center by dialing *015-9*.

Telex Charges

There is no minimum time charge for individual Telex calls between New York City and Canadian subscribers. Instead, there is a flat connection charge of 50¢ for each completed call, plus a particular pulse rate, based on airline mileage, which is applied for the actual time the connection is held intact. The pulse rate, having no relation to the telegraph transmission speed, is expressed in ppm (pulses per minute) and the charge for each pulse is $2^1/_2$¢. In addition, there is a $35.00 monthly charge for the subscriber equipment. There is no charge for calls to Western Union other than the regular rate for telegrams or cablegrams.

For example, a pulse rate of 15 ppm is applied for a New York City–Montreal call and 30 ppm for a New York City–Vancouver, B. C., call. Therefore, the connection and pulse-rate charge for a 1 minute New York City–Montreal call is 50¢+(15×$2^1/_2$¢) or $87^1/_2$¢ and for the New York City–Vancouver call it would be 50¢+(30×$2^1/_2$¢) or $1.25. If these calls were held for a 2-minute period,

the charges would be $1.25 and $2.00, respectively. The connection and pulse-rate charges are assessed to the calling subscriber on two 5-digit counters individual to each subscriber line and are shown in Fig. 6.

Telex Exchange Operation

New York, as well as the exchanges in Canada, is equipped with a switching system which has been specially designed for teleprinter exchange service. While employing different circuitry, the system uses a number of equivalent telephone-exchange functional components such as preselectors, group selectors, final selectors, repeaters, etc. Fig. 7 shows a simplified theory layout of the New York Telex Exchange.

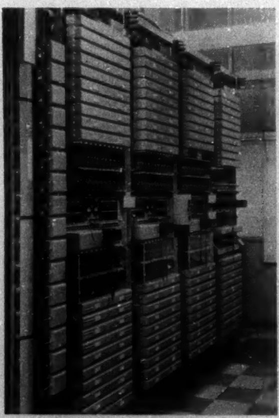

Fig. 8. Left to right, one rack for 20 final selectors, three racks of 40 local preselectors, and one rack of 20 long-distance preselectors

The operation of the exchange equipment will be covered by describing the functions which occur for setting up the typical New York City to Vancouver, B. C., call previously used in the brief explanation of how a Telex connection is established. The description for a northbound call, outgoing from New York and incoming at Vancouver, also will be typical of southbound calls from various Canadian exchanges to New York City. Photographs of the exchange-equipment units also will be referred to at appropriate points throughout the discussion. The multiple wiring and grouping arrangement of the equipment is not essential to a preliminary understanding of the exchange operation and is discussed later.

PRESELECTORS

Fig. 8 shows a group of preselector racks where the loop from each subscriber is terminated. Each subscriber's preselector consists of control equipment located in a subscriber bar and an associated preselector (stepping) switch capable of connecting to any one of ten GS/TZM (group selectors/time-zone meters). Each of the first three preselector racks accommodates 40 local subscribers (or tie-line positions) which are operated on a loop basis using make-break signaling. A different type of preselector rack, serving 20 long-distance subscribers, has additional control equipment for operating 2-wire polar over physical or carrier facilities for longer distances. In the latter case a d-c converter panel is required at the terminal of the distant subscriber to provide an equivalent termination between the line facilities and the conventional subscriber loop.

When the subscriber's set is idle, a current of about 5 ma (milliamperes) flows in the loop in a direction to keep the teleprinter motor cut off and the subscriber's remote control (dial) unit locked. As a subscriber initiates a call by depressing the start button on the remote control unit, equivalent to removing a telephone from the hook, the current in the loop is increased to 60 ma. This causes the subscriber's 11-point preselector switch in the exchange to leave its home position and seek connection to any one of ten GS/TZMs which may be idle. If all ten of these units are in use, the preselector switch steps to the 11th point, returns a busy signal to the subscriber and then restores to its home position.

GROUP SELECTOR/TIME-ZONE METER

The New York Exchange is equipped with 32 GS/TZMs and Fig. 9 shows five of these units per rack, with the group selectors located in the upper section and the five associated time-zone

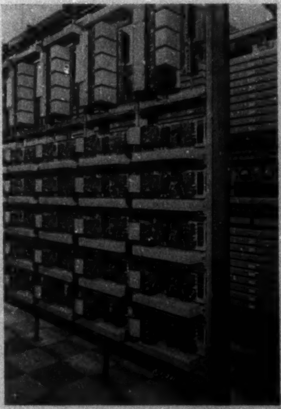

Fig. 9. Group selectors/time zone meters

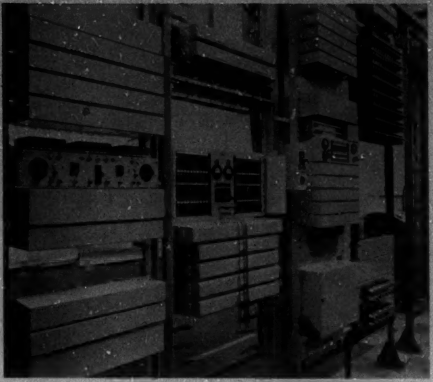

Fig. 10(left). Left to right, pulse generator, trunk repeater, and central test-transmitter racks

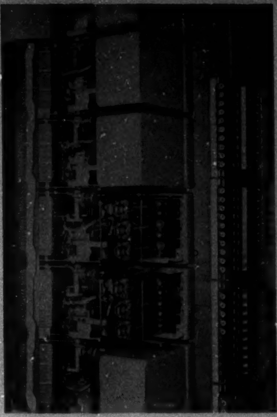

Fig. 11 (right). Group selectors associated with incoming trunk repeaters

meter units mounted below. The group selector is a 2-motion decade-type (stepping) switch with associated relay controls and the switch, having ten vertical levels (rows) and ten rotary points in each level, provides 100 outlets for three circuits designated as SEND, RECEIVE, and TEST, the latter being used for control purposes.

The associated time-zone meter is for the purpose of recording, by means of two stepping switches and associated relay controls, the first four dial digits, or less, in order to apply the proper charge for each call. In doing so, the proper metering pulse-rate conductor, i.e., 15, 18, 30 ppm, etc., is picked up from the pulse generator rack shown in Fig. 10 and is passed back over a separate conductor through the preselector switch to the subscriber's two individual connection and pulse-rate counters. After the dialing sequence and when a free-line signal has been given to the calling subscriber which indicates a completed call, both counters are stepped on a prepulse and thereafter only the pulse-rate counter responds to the metering pulses obtained from the pulse generator rack. The time-zone meter can be strapped to cancel and return a busy signal on certain calls which are to be rejected for special reasons. Also calls to the tie line or information positions at New York are recognized by this unit as "free" calls, for which neither counter is allowed to operate.

When the subscriber's preselector switch has made connection with an idle GS/TZM, which is almost simultaneous with the release of the start button, a go-ahead-dial signal is returned to the subscriber set. This signal is an interruption in the subscriber's loop current for about 25 milliseconds which unlocks the dial unit and brings up a white visual indicator in the remote-control unit, providing an indication that dialing can begin.

As the subscriber begins the dialing sequence, the group-selector switch in the GS/TZM is operated by the dial pulses of the first digit, which for a long distance call would be *0*, to the tenth level. The switch then free-hunts or self-steps horizontally over the ten rotary points on this level and stops on the first idle point corresponding to an outgoing or 2-way trunk repeater to the Montreal Exchange. A busy signal also will be returned to the subscriber at this point if all available trunk circuits are in use. Between the dialing time of the first and second digits, the trunk circuit to Montreal is tested by means of a revertive pulse which is described in the following paragraphs on the Telex trunk repeaters.

TELEX TRUNK REPEATERS

The 12 trunk circuits which connect to the Montreal Exchange are terminated in three types of repeaters designated as outgoing, 2-way and incoming, which are located on a rack shown in Fig. 10. The three types of repeaters permit the trunk circuits to Montreal to be operated on a 4/4/4 basis, which denotes the outgoing, 2-way, and incoming seizure priority for establishing a Telex connection. For example, the four outgoing trunk circuits may be seized only for northbound calls; the four 2-way circuits for calls in either direction, and the four incoming circuits for southbound calls only. A jack field and associated controls for testing individual trunk circuits is located in the center of the rack.

In addition to the switching controls for seizure of the trunk circuit, each repeater contains two polar telegraph relays which repeat the telegraph signals and dial pulses on a 2-wire polar basis between similar telegraph relays in the subscriber's preselector located in the exchange and the sending and receiving legs of the carrier channel terminal equipment. When a trunk circuit is unseized, the spacing (positive) polarity is applied in both directions.

Returning now to the typical northbound call, as the GS/TZM, which was previously described, stops on the point of an idle outgoing or 2-way repeater after the first digit has been dialed, the sending leg of the carrier trunk circuit to Montreal is reversed to the marking (negative) polarity. This seizure signal is received in the Montreal Exchange on an incoming or 2-way repeater having an associated group selector. If the trunk facility and group-selector equipment is in proper working order, the Montreal repeater returns a revertive pulse of approximately 25 milliseconds to the New York Exchange. Reception of this signal in New York momentarily operates the receiving relay in the Telex repeater to the marking polarity and then back to spacing, verifying circuit and equipment continuity for the reception of dial digits. Failure to properly test a trunk circuit in this manner instantly produces a busy signal to the calling subscriber, removes this particular trunk circuit from service, and operates an exchange alarm.

As the second and third digits are dialed by the New York subscriber in the typical *036-292* call to Vancouver, the second digit, *3*, sets the group selector at Montreal, as shown in Fig. 5, to the third vertical level where it free-hunts, seeking an idle outgoing or 2-way repeater to Winnipeg. When the connection is made to such a repeater, the trunk circuit between Montreal and Winnipeg likewise is tested by means of the revertive pulse as previously described. Following this the third digit, *6*, is used in a similar manner at Winnipeg to extend the call to Vancouver. The call now enters the Vancouver exchange in an incoming or 2-way repeater having an assigned group selector as shown in Fig. 11, which is pulsed by the fourth digit, *2*, to the second vertical level. Between the dialing time of the fourth and fifth digits, the group selector free-hunts over the rotary points in level *2* and connects to the first idle final selector.

For each 100 subscriber lines in an exchange a rack of 20 final selectors, as shown in Fig. 8, is provided for handling incoming calls to this group of subscribers. The final selectors also use the 2-motion decade-type 100-point stepping switch and associated relay controls, but unlike the group selectors, they do not free-hunt in a horizontal direction. Instead the final selectors are pulsed vertically and then horizontally by the remaining two dial digits to make connection to any one of 100 subscribers served by this rack.

As the group selector seizes an idle final selector and the dial digits *92* are received in the Vancouver exchange, the circuit is extended to the called subscriber's preselector switch. If the Vancouver subscriber is idle, as indicated by the preselector switch being in the home position, the relay controls of the preselector function to reverse the 5 ma flowing in the loop. This reversal of current actuates the polar motor-control equipment in the subscriber's set, which turns on the teleprinter motor, operate lamp, and also increases the loop current to the 60-ma working level.

Provided the loop current has been raised to the working level, the called subscriber's preselector in the Vancouver exchange will now return the free-line signal to the calling subscriber's preselector in the New York Exchange. This is a reversal of transmission polarity from spacing to marking in the east-bound direction. As this signal is received at New York the 60-ma current flowing in the calling subscriber's loop is reversed, causing the teleprinter motor and operate lamp to be turned on and the dial unit to be shunted from the loop circuit. As the connection is completed, the calling subscriber's connection counter is stepped one unit and the associated pulse counter begins recording the assigned pulse-rate charge for this call. Starting of the calling subscriber's teleprinter motor now permits the exchange of answer-back sequences previously described.

DISCONNECTING

Either the calling or called subscriber may terminate a Telex connection by depressing the STOP key on the remote-control unit for about 1 second. This transmits a steady-spacing polarity to the distant end, longer in length than normal teleprinter-signal combinations. Regardless from which terminal such a disconnect signal emanates, it is recognized by the calling subscriber's preselector, in this case New York, which in turn transmits a steady spacing signal through the GS/TZM, outgoing or 2-way repeater at New York, through the Montreal, Winnipeg, and Vancouver exchanges. This signal effects a release of the trunk circuits and switching equipment in the various Telex exchanges in the same sequence in which the connection was originally established. As the disconnect takes place, the subscriber sets at both ends of the circuit are restored to the idle condition by having the teleprinter motor and operate lamp turned off and the dial unit at the calling station relocked.

DIALING WESTERN UNION

Referring to Fig. 7, the local position preselectors are connected through matching relays, *C*, directly to specified levels on the GS/TZM switches, effecting a savings in final-selector equipment. As a New York subscriber dials *1*, *3*, etc., the GS/TZM switch is stepped vertically to the proper level where it then free-hunts and connects to the first idle position.

Other Exchange Equipment

The following paragraphs will briefly describe the operation and arrangement of other equipment in the exchange not explained in the foregoing description of a typical connection.

PULSE GENERATOR

The various pulse rates, one of which is picked up by the time-zone meter for each chargeable call to step the subscriber's pulse-rate counter, is supplied from the pulse generator rack shown in Fig. 10. This rack contains two pulse generators, one working and one fall-back, a changeover frame and 18 output relays, producing various outputs from 1 up to 36 ppm. In case of equipment failure, the companion pulse generator is automatically placed in operation.

The individual pulse generator consists of two polar telegraph relays having an R-C oscillatory circuit adjusted for a basic output frequency of 360 operations per minute. This output is used to drive several groups of switching relays, in a frequency-reducing network, which in turn drive 18 output relays corresponding to the required pulse rates. For the pulse and no-pulse intervals, a combination of negative battery and ground potential, respectively, is applied from the contacts of each output relay to the various pulse-rate leads which connect to the time-zone meters. The absence of this combination for any length of time enables an automatic pulse-control monitor to detect an open, short, or ground on any of the pulse leads.

In addition to the tariff function, a selected number of these pulse leads are used, instead of electronic timers, to actuate alarm and control circuits for abnormal exchange functions. For example, when a subscriber depresses the start button and does not dial a number, the exchange equipment is restored to normal after about 3 minutes by a control circuit which absorbs three of the 1-ppm pulses.

CENTRAL TEST TRANSMITTER

The New York Exchange is equipped with a central test transmitter, also shown in Fig. 10, which automatically transmits a choice of three types of tests for the use of maintenance personnel in checking local subscriber equipment or transmission over Telex trunk circuits. The characters for the test transmission are programed by relays from a drum-type distributor and each test can be transmitted simultaneously to five different lines.

When the digits *5*, *6*, or *7*, respectively, are dialed from a local subscriber set, the following tests are continuously provided by this transmitter:

1. A printing test utilizing all the lower and upper case teleprinter characters.
2. An unbiased "quick brown fox" sentence.
3. Five lines of "quick brown fox" in which one half of the sentence is alternately spacing and marking bias. Each line is prefixed with 0, 20, 30, 35, or 40% to indicate the amount of bias being transmitted.

Canadian exchanges may also obtain

these three tests automatically from New York by dialing *015-5*, *015-6*, and *015-7*, respectively, in order to check northbound trunk-circuit transmission.

EXCHANGE MULTIPLING AND GROUPING

The rack multipling between the stator points of all group and final-selector switches is made with 15-conductor ribbon wire which can be seen in Fig. 11. The ten points on the preselector switches are multipled in groups of 20 switches each which are wired to ten GS/TZMs and some of the latter are shared by several preselector groups. Ten group selectors are multipled in one group. Where the number of outlets exceed the ten points on the vertical level of these switches, such as levels *1* or *3* for the Western Union receiving positions or level *2* for the input to the final selectors, a mixing-plan arrangement is used and in some cases several groups of group selectors share the same outlet.

Life Characteristics of Carbon-Film Resistors after 12,000 Hours of Operation

H. BRANER
NONMEMBER AIEE

J. L. EASTERDAY
NONMEMBER AIEE

THE DEVELOPMENT of carbon-film resistors since World War II has provided the electronics industry with a reasonably priced semiprecision resistor.[1,2] The film resistors are smaller, lighter, cheaper, and have better frequency characteristics than precision wire-wound resistors. They are not as accurate as precision wire-wound resistors, and the temperature coefficient is still undergoing improvement, but the film resistor can perform an important function in filling the needs for a semiprecision resistor.[3]

Considerable effort has been devoted to determining the quality of these resistors, and minimum standards have been established, such as those found in *MIL-R-10509*.[4] However, little has been done to determine the long-term stability of carbon- and borocarbon-film resistors.

The purpose of a research program, conducted at Battelle Memorial Institute under the sponsorship of the U. S. Army Signal Research and Development Laboratory, Fort Monmouth, N. J., was to investigate the stability or drift of carbon-film resistors when operated at rated load in an ambient temperature of 70 C (degrees centigrade) for 12,000 hours.[5] Past work in this area has been confined primarily to the study of small sample sizes, various operating conditions, and relatively short periods of time such as 1,000 or 2,000 hours. Such work is generally done by the manufacturer to check his production, or for military qualification and acceptance tests. The 18-month program conducted by Battelle was designed with large sample sizes and carefully controlled test conditions so that statistical estimates of infinite population behavior were practical.

Laboratory Investigations

SAMPLES

The carbon-film resistor types investigated were 1/2-watt 237,000-ohm (critical values) resistors, and 1/2-watt borocarbon resistors with a nominal resistance value of 100,000 ohms. Four brands of resistors were included; three of these were deposited-carbon film and consisted of two sample groups of 250 resistors each and one sample group of 500 resistors. The fourth brand of resistors represented was a sample of 500 borocarbon resistors. Three of the brands investigated were supplied in a molded case, while the resistors of a fourth manufacturer were solder sealed in a ceramic tube.

TEST PARAMETERS

The resistors were operated at full rated load in an ambient temperature of 70 C for a period of 12,000 hours, with one exception. The borocarbon-resistor test was terminated after 9,500 hours of operation.

Resistance values were read after the resistors were installed in the chambers but were still at room temperature. Then heat was applied and the resistors were continuously monitored until the resistance values appeared to be stabilized. This required three to four hours. After the resistors were stabilized at 70 C, readings were taken which were used as the initial conditions against which all subsequent data were compared. After these readings were taken, the excitation voltage was applied in cycles of $1^1/_2$ hours on, and 1/2 hour off. At the end of the evaluation, the ambient temperature was reduced to room temperature and resistance deviations again recorded. The chambers were then opened for general observations and to determine the modes of failures.

EQUIPMENT AND INSTRUMENTATION

One of the important phases of this program was the design and construction of suitable temperature chambers. The factors considered in designing the temperature chambers were the effects of heat radiation from one resistor to another, air circulation, temperature gradient, and temperature control.

Optimum mounting distances between resistors were determined by preliminary tests. It was found that a horizontal spacing of 2 inches and a vertical spacing of 4 inches between resistors resulted in a maximum temperature rise of 0.3 C above ambient at a point midway between two resistors. Radiation baffles were provided by constructing the trays in the form of an open gridwork which resulted in a rectangular compartment for each resistor. Each chamber contained five of these trays with 100 resistors in each tray. Effects of heat interaction between resistors was further minimized by staggering the resistor positions in the vertical plane.

The additional heat required to maintain a 70 C ambient was introduced by

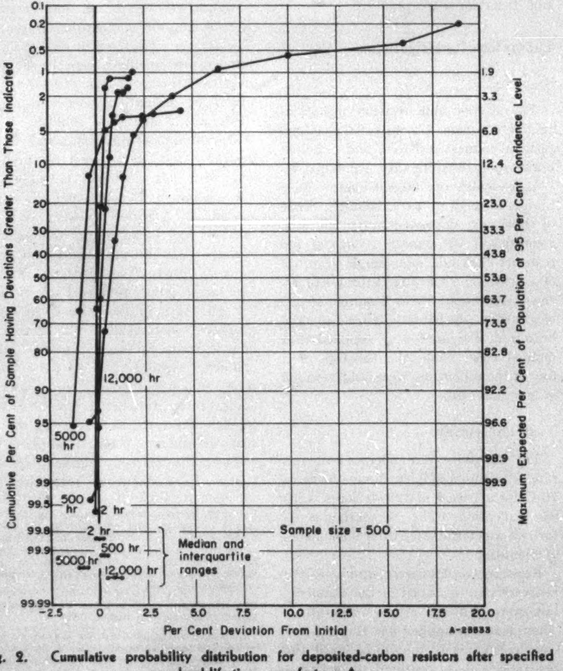

Fig. 2. Cumulative probability distribution for deposited-carbon resistors after specified load-life time, manufacturer A

an air flow, counter in direction and equal in magnitude to the natural convection currents, thus neutralizing the latter's effects.

Further effects of temperature irregularities were minimized by using a randomized distribution of samples throughout the oven. In addition, the load cycling was planned so that 75% of the resistors were energized at all times and that the energized resistors were always distributed throughout the chamber. The chamber temperature was maintained at 70 ± 5 C and the ovens had a gradient of 3 C. These temperatures were monitored with 15 thermocouples in each chamber, placed in groups of three for each tray.

The other important equipment problem was that of instrumentation. It was desirable to take the resistance readings of each group of 125 resistors during the 1/2 hour "off" portion of the energizing cycles, thus completing the data for the 500 specimens in a 2-hour period. To accomplish this aim, Battelle designed and built an automatic-scanning device which selects the components in a specified order and connects each component to a Barnes deviation bridge. The deviation bridge reads the per cent of resistance deviation from a standard (nominal resistance value in this case). The output of the deviation bridge is fed through a binary encoder to an IBM (International Business Machines Corporation) key punch. The key punch operates auto-

matically, punching all fixed identification (such as project number and date) from a master card, resistor identification from information supplied by the scanner, and per-cent resistance deviation as measured by the Barnes bridge. With this automatic data-taking equipment, resistance-deviation readings can be taken at the rate of 1,400 readings per hour.

In order to determine the precision of the equipment, an analysis of variance was performed on 100 observations of per-cent deviations from nominal of ten resistors, each read ten times. From the results of this analysis we can expect 95 % of the measurements to have a measuring error of less than 0.5% deviation from nominal (assuming a normal distribution of errors).

Data Presentation

The data, showing per-cent resistance deviation from nominal, on the original IBM cards were processed through an IBM *650* computer. The computer was programed to convert per-cent deviation from nominal to per-cent deviation from initial and to group the results in class intervals of 0.5%. The deviations from initial were then arrayed from the most negative deviation to the most positive deviation. The ultimate objective of this procedure was to present the results in the form of cumulative frequency distributions of resistance deviations from initial plotted on arithmetic probability paper. A brief discussion of this type of graphic presentation is found in the Appendix.

Another type of presentation is used also. This consists of plotting the "per cent of sample deviating from initial value by greater-than-specified amount" versus time in hours. The "specified amounts" are, in effect, arbitrary failure criteria. The values chosen for these failure limits were ±1%, ±2%, and ±5% deviation from initial.

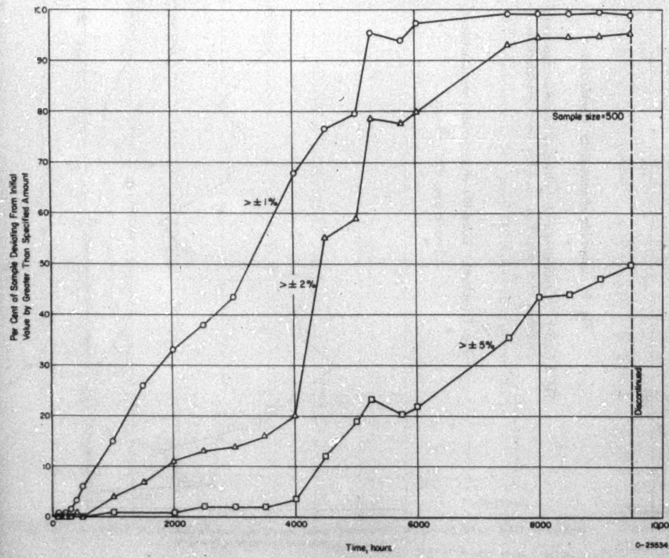

Fig. 7. Load-life characteristic, manufacturer D

Discussion of Results

The film resistors evaluated in this program displayed different aging characteristics depending on the manufacturer. The only generalizations to be made are that the resistors stabilize early in life and deteriorate at a constant rate until wear-out is reached.

Observing the ±2% deviation curve in Fig. 1, it is seen that the resistors of manufacturer *A* have a failure rate of approximately 0.7% per 1,000 hours until the 11,500-hour point. The change of failure rate at this point seems to indicate that a wear-out point has been reached. The erratic fluctuations noted in the curves are not necessarily indicative of erratic resistor behavior. As mentioned in the section on "Data Presentation," the percent deviations were divided into class intervals of 0.5%. Therefore, a large fluctuation on the curve may indicate that a quantity of resistors had a deviation change of 0.1 to 0.5% from the previous reading, thereby causing them to fall outside or just inside the fixed limit assigned to the particular curve. Cumulative distributions of resistance deviations at four representative times are shown for manufacturer *A* in Fig. 2. The linearity and the steepness of the slope of the three curves grouped about zero-per-cent deviation indicate tight distributions centered near zero for the first 5,000 hours of life. By 12,000 hours, however, 17 resistors had open-circuited, four more had deviations from initial which were greater than 30%, and a general increase was noted in the spread of deviations as evidenced by the graph.

The resistors of manufacturer *B* exhibit the best characteristic of the four types investigated in this program. After an apparent stabilization period of 100 hours, the average failure rate was approximately 0.13% per 1,000 hours (based on the ±2% failure criteria) through the 12,000-hour period. No wear-out point was noted. Figs. 3 and 4 illustrate the characteristics of these resistors. The distributions of deviations are normal and quite narrow, with 98% of the sample remaining within 2% of the initial deviation (see Fig. 3).

One mishap occurred during the evaluation of these resistors. As noted in Fig. 3, the sample size changed abruptly from 500 to 250 at approximately 9,000 hours. This change was due to an unreliable power supply. The voltage regulator failed in such a manner as to apply a high voltage to 250 of the resistors, thereby damaging them to an extent requiring their removal from the evaluation.

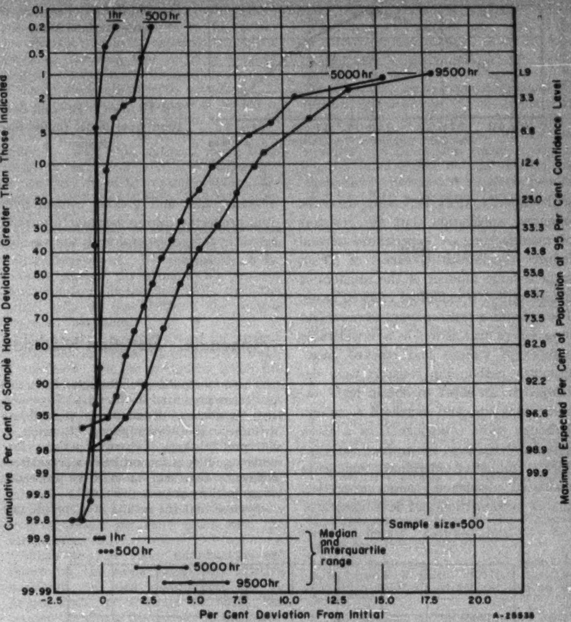

Fig. 8. Cumulative probability distribution for deposited-carbon resistors after specified load-life time, manufacturer D

From the remaining sample of 250, two of the resistors of manufacturer *B* open circuited during the evaluation, and 29 of them exhibited a series of very fine cracks, similar to crazing, on the outer surface.

The resistors of manufacturer *C* exhibited a failure rate of 2.3% per 1,000 hours from 500 hours to 11,500 hours. At 11,500 hours a wear-out type of characteristic is apparent, as noted in Fig. 5. A comparison of the 1% failure criteria for the different types of resistors shows that more of these resistors drift outside the 1% limit than do the resistors of manufacturers *A* and *B*.

The cumulative distributions of deviations are shown in Fig. 6. The interquartile ranges are somewhat broader than for the other carbon-film resistors. A large number of failures and excessive deviations are apparent from the distribution of the deviations at 12,000 hours: 29 open circuits, two short circuits, six resistors with deviations from initial greater than ±30% among the 500 resistors on test. Several case failures were also noted. These were characterized by cracks around the end caps on 63 resistors, one ruptured resistor, and evidence of severe internal heat on nearly all the resistors. The excessive heat caused the central portion of the case to turn white and powdery.

The borocarbon resistors of manufacturer *D* exhibited an inferior aging characteristic in comparison with the other carbon-film resistors. The average failure rate is approximately 10% per 1,000 hours, based on a criterion of deviations in excess of ±2% being considered failures (see Fig. 7). No wear-out point was in evidence, nor was a stabilization point noted. This test was discontinued at 9,500 hours because of the excessive number of large deviations as indicated by the cumulative probability distributions for 5,000 and 9,500 hours shown in Fig. 8.

Conclusions

The results of this program indicate that the carbon-film and borocarbon-film resistors evaluated in this program will not meet long-life high-stability requirements. The resistors of manufacturers *A* and *B* have fairly reasonable stability

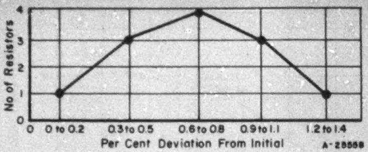

Fig. 9 (left). Per cent of deviation from initial

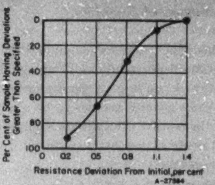
Fig. 10 (right). Per-cent deviation from initial (upper-class limit)



with respect to drift, depending upon the intended application, but the resistors of manufacturer *A* experienced several failures (deviations in excess of 30%), while a large number of the resistors of manufacturer *B* exhibited cracked cases. The remaining resistor types were subject to excessive drift as well as a considerable number of failures and cracked cases. Pyrolytic carbon-film resistors were developed in an effort to obtain high stability, long life, and increased accuracy. Although these components, as a class, were unsatisfactory, the authors feel that since a number of individual components evaluated displayed these properties, further investigation and development of resistor cases and greater control over film properties during manufacture could result in a fixed resistor with superior life characteristics.

Appendix. Statistical Methods

The major portion of the data from this project is presented in the form of cumulative frequency distributions plotted on arithmetic probability paper. In order to interpret this type of chart properly, a clear understanding of the nature of a cumulative frequency distribution and of the properties of probability paper is essential.

Assume that the results of a specific test performed on a sample of 12 resistors are as follows:

Resistor Number	Per-Cent Deviation from Initial
1	0.9
2	1.1
3	0.8
4	0.4
5	1.0
6	0.3
7	0.0
8	0.7
9	0.3
10	0.6
11	0.8
12	1.3

An ordinary frequency distribution constructed from these data might look like this:

Per-Cent Deviation from Initial	Number of Resistors
0–0.2	1
0.3–0.5	3
0.6–0.8	4
0.9–1.1	3
1.2–1.4	1
Total	12

In actual practice it would be impractical to construct a frequency distribution from so small a sample size. However, for the sake of the illustration, let us plot this distribution on ordinary arithmetic graph paper (Fig. 9).

This is the familiar normal distribution. If two additional columns are now added to the previous table, one showing the accumulated number of resistors having deviations from initial greater than the upper class limit, and the other showing this accumulated number as a per cent of the total number of resistors, the table would appear as follows:

Per-Cent Deviation from Initial	Number of Resistors, f_0	Number Greater Than Upper Limit, $n-f_0$	Per Cent of Total Greater Than Upper Limit, $\frac{n-f_0}{n}$
0–0.2	1	11	91.7
0.3–0.5	3	8	66.7
0.6–0.8	4	4	33.3
0.9–1.1	3	1	8.3
1.2–1.4	1	0	0
Total $n=12$			

The column showing the accumulated number of resistors greater than the upper-class limit is known as the "greater than" cumulative frequency distribution. The

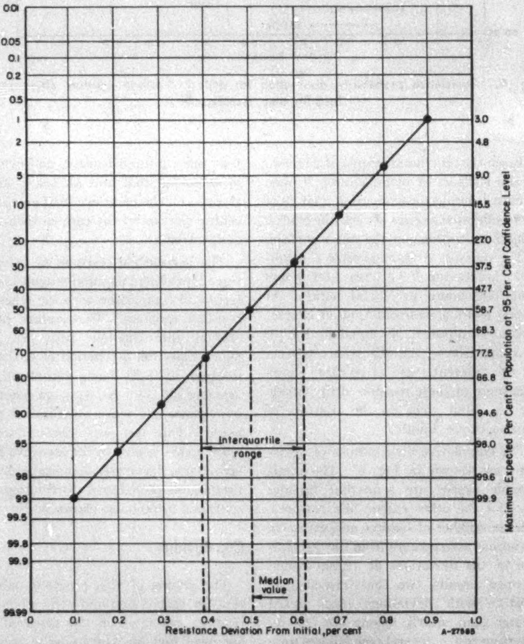


Fig. 11. Hypothetical cumulative distribution of resistance deviation from initial for 100 resistors after a specified test

column showing this cumulative frequency as a per cent of the total number of resistors is called the cumulative probability distribution because it represents an unbiased average estimate of the per cent of the population having deviations from initial greater than the upper class limit. If this distribution were plotted on arithmetic graph paper, an ogive would be described by the curve. This is shown in Fig. 10.

A special type of graph paper has been developed which is essentially arithmetic paper with the vertical axis marked off in per cent. However, since the cumulative probability curve of a perfectly normal distribution always yields an ogive of the same proportions, it was possible to adjust this per-cent scale by elongating the divisions in the middle and compressing the scale at the ends so that a normal ogive becomes a perfectly straight line. One other modification is necessary in the construction of probability paper. Statistical theory states that the entire range of population values cannot be estimated from a sample size which is smaller than the whole population. Therefore, the probability distribution, being a sample estimate of the population per cents, can never estimate the 100% or 0% point of the population. Thus the per-cent scale on arithmetic probability paper can never reach zero or 100%; consequently, the lowest value resistor and the highest value resistor cannot be shown on a cumulative probability distribution plotted on probability paper.

Fig. 11 is a graph of a hypothetical cumulative probability distribution of 100 resistors plotted on arithmetic probability paper.

A great variety of information is available from a graph such as this. Most apparent is the degree of normalcy of the sample distribution. This is evidenced by the "straightness" of the line, a straight line indicating a normally distributed sample. Any deviation from a perfectly straight line indicates an abnormally distributed sample, although in judging the linearity of the curve more weight must be given to the central portion of it than to the extremes. This is a result of the fact that in most random samples some extreme values will occur even if the population is perfectly normal.

A second type of information yielded is the resistance deviations within any chosen percentile range of the sample. Thus, for example, the 50% range (interquartile range) lies between the 25% and 75% points of the line, or, in the example shown, between 0.39% and 0.62% deviation from initial value.

If tolerance criteria are known, then the per cent of the sample exceeding tolerance can be determined. For example, if in our present example the tolerance for per-cent deviation from initial is 0.70%, then the graph tells us that 12% of the sample exceeded this value.

The graph can also be used for making population inferences at a specified confidence level. On the exemplary graph the maximum expected population per cent having deviation from initial greater than a specified value at the 95% confidence level is shown on the right-hand scale. Thus in our previous example where 12% of the resistors exceeded tolerance, the maximum expected population per cent exceeding tolerance at the 95% confidence level would be about 17.8%. The population estimate from a sample per cent varies with the sample size.

When two or more distributions are shown on the same graph, the relative variability of each distribution can be judged from the slope of the line. The greater the slope, the greater is the variability.

As mentioned before, the 0% and 100% points cannot be plotted on the graph. Hence the lowest value resistor in the sample of 100 and the highest value resistor are not shown, resulting in a curve which goes from 1% to 99% of the sample. On some of the charts in this paper it will be noted that more than one resistor is omitted from each end of the curve. When this occurs, it can be safely assumed that all, or all but two, of the resistors omitted had deviations from initial which exceeded the limits shown on the chart. If, for example, a graph of 100 resistors starts at the 3% of sample point and goes to only the 95% of the sample point, it must be assumed that at least four resistors had deviations greater than the highest value shown on the abscissa and that at least two resistors had deviations less than the lowest value shown on the abscissa.

Rapid Determination of Corona Loss From Voltage-Charge Diagrams

H. S. DIXON
MEMBER AIEE

THE MEASUREMENT of a-c corona loss in laboratory test setups is frequently necessary when the magnitude of the loss is so small that wattmeter instruments cannot be used. An accurate, rapid means using only one measurement from a voltage-charge diagram is presented in this paper.

Voltage-charge diagrams were first used by Ryan to determine corona loss.[1] Time-consuming photography of oscilloscope patterns and planimetry thereof are required. From a laborious point-by-point analysis of corona voltage-current oscillograms, Karapetoff secured the corona loss.[2]

For magnetic samples, a method of determining hysteresis loss using three measurements from a hysteresis loop has been presented by Conover.[3]

Loss Determination Method

Following Ryan's voltage-charge method and using the basic circuit shown in Fig. 1, the diagrams shown in Fig. 2 were secured as the applied voltage was increased. Careful examination of a diagram such as that of Fig. 2(B) or 2(C) shows that the diagram consists essentially of a parallelogram plus two half-ellipses as shown in Fig. 3.

The area A of the complete diagram in terms of the quantities defined on Fig. 3 is

$$A=2E_iH+\frac{\pi H}{2}(E_m-E_i)\text{ volt-divisions}$$

This reduces to

Paper 59-24, recommended by the AIEE Indicating and Integrating Instruments Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted March 31, 1958; made available for printing November 18, 1958.

H. S. DIXON is a Consulting Engineer, Berkeley, Calif.

The work described in this paper was performed at the High Voltage Engineering Laboratory, Purdue University, as a part of a Ph.D. thesis under the able guidance of Dr. C. S. Sprague.

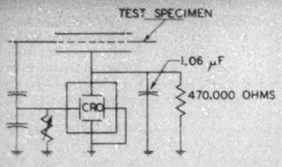

Fig. 1. Corona loss measurement circuit

$A = H(1.5708E_m + 0.4292E_i)$ volt-divisions

In terms of charge and energy A_e

$A_e = Q(1.5708E_m + 0.4292E_i)$ joules per cycle at the particular test frequency used

where Q is the charge in coulombs as determined from H. Consequently the energy loss per cycle at the test frequency is readily obtained from the applied voltage, the instantaneous corona initiation voltage, and a measurement of the vertical distance across the diagram when calibration of the vertical distance is made in coulombs. An example of such a calculation is given in the Appendix.

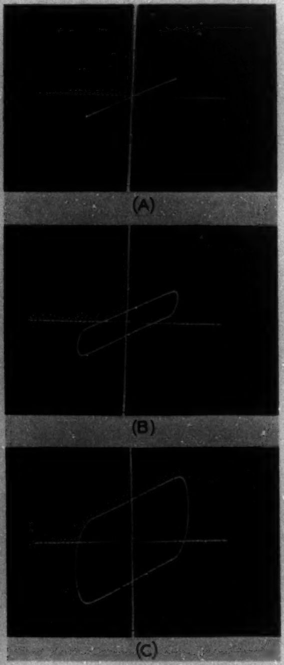

Fig. 2. Voltage-charge diagrams for three different voltages

A—35.2 kv, no corona
B—40.6 kv, corona present
C—47.2 kv, corona present

Unsymmetrical Diagrams

In the case of unsymmetrical diagrams such as shown in Fig. 4 which were secured with a positive d-c bias in series with the alternating applied voltage, the same equation for securing the a-c energy loss may be used. In this case H is measured so as to represent the average vertical distance between the two nearly straight line segments of the diagram. This procedure is equivalent to using the average of the major axes of the two half-ellipses.

Stabilization of Diagrams and Accuracy

Because of the extremely fast pulses or bursts during the negative half-cycle a-c corona, it is necessary to place a resistor across the integrating capacitor so as to stabilize the diagram on the oscilloscope so H can be measured. This resistor also drains off the charge that would otherwise accumulate on the capacitor as a result of the rectification action of corona.

This resistor also drains off some of the capacitor charge placed thereon during the corona bursts. Hence, the indicated value of H is reduced from its correct value by the presence of the resistor. However, if the time constant for the leakage of this charge is made sufficiently large compared to the half period of the applied voltage, the error is small and can readily be evaluated.

Assuming that during a half-cycle, the corona charge is placed on the capacitor by an instantaneous burst, it leaks off for an equivalent time of one half-period before the effect of this charge is measured by the distance H at the center of the diagram. Accordingly, the ratio of the charge measured q_m to actual corona half-cycle charge q_c is

$$\frac{q_m}{q_c} = e^{-\frac{t}{RC}}$$

where RC is the time constant and t is the half-period for the particular frequency used. For the apparatus used, the ratio q_m/q_c was 0.984, which means that H is 1.6% less than it would be if no stabilizing resistor were used. The measured power loss needs to be increased by 1.6%.

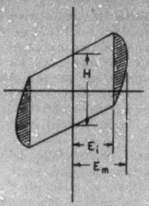

Fig. 3. Representation of area of symmetrical diagram by a parallelogram and two half-ellipses

E_i = corona instantaneous initiation voltage, volts
E_m = maximum instantaneous applied voltage, volts
H = average vertical distance across parallelogram, divisions

For the apparatus used, the capacitance between the cylinder and ground was calculated to be less than $1.0(10^{-4})$ microfarads so that its shunting effect on the 1.06-microfarad integrating capacitor was negligible.

To check the accuracy of the method of arbitrary representation of the corona voltage-charge diagram as a parallelogram plus two half-ellipses, the diagrams of Figs. 2 and 4 were planimetered. The calculated areas using measurements of H, E_i, and E_m from the diagrams were

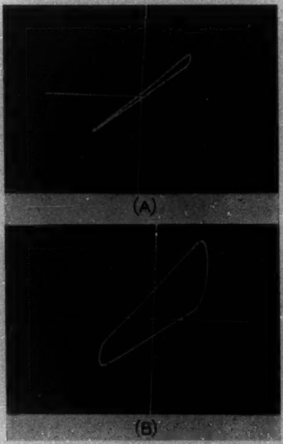

Fig. 4. Unsymmetrical voltage-charge diagrams

A—Triangular diagram
B—Quadrilateral diagram

the same as those secured by planimetry except for the largest area where the result was within the range of readings from individual traverses of the planimeter. Consequently, the method of calculating areas from the arbitrary representation is as accurate as planimetry, or is within 1%. Since this method of arbitrary representation of the diagrams is accurate to within 1%, this per cent error must be added to the per cent error in calculating A_e resulting from the combination of individual errors in measuring H, E_m, E_i, and the calibration data E_c, H_c, and C.

Conclusion

An accurate, rapid method of determination of corona loss from voltage-charge diagrams from one measurement on the diagram has been presented.

Appendix

Example of Calculation

The loss calculation for the following data, secured using a 1/8-inch-diameter rod centered in a 29-inch-long $6^1/_2$-inch-diameter cylinder, is given:

E_i=34,700 volts, corona instantaneous initiation voltage

E_m=35,500 volts, maximum instantaneous applied voltage

H=4.0 divisions, vertical distance across parallelogram

The data for the vertical calibration of the oscilloscope, and the integrating capacitor, where E_c is the rms voltage applied across the capacitor and H_c is the length of the vertical trace on the oscilloscope face, are

E_c=0.0190 volt

H_c=43.0 divisions

C=1.06 microfarads

Consequently

$Q=C2\sqrt{2}(E_c/H_c)H=1.06(10^{-6})(2\sqrt{2})(0.0190/43.0)(4.0)=0.0053$ microcoulomb per cycle

So

$A_e=0.0053[1.5708(35{,}500)+0.4292(34{,}700)]=375$ microjoules per cycle

The corona power loss at 60 cycles per second is

$P_c=60(375)(10^{-6})=23$ milliwatts

which is accurate to only two significant figures considering the accuracy of this particular value of H.

A Talk-Back System for Educational Television

R. C. NORTON
NONMEMBER AIEE

J. B. DAVIDSON
NONMEMBER AIEE

TODAY the magic of television takes a teacher instantly to as many classrooms as desired. She appears before vast numbers of pupils not only with her voice, but with her material and her gestures, instructional ability, and personality intact. The principal missing element is the ability to know her pupils and to gage her pace by their reactions. Unseen and unheard, they lack presence.

In Cortland, N. Y., this major weakness of educational television is being overcome to a large degree by the talk-back system. This system, designed and provided by the New York Telephone Company, makes every pupil "present" to the studio teacher. By simply pushing a button she can instantly converse with any pupil in any classroom. Lamps on a panel before her indicate when the pupil has a question and stay on until she chooses to listen to his question. Thus hundreds of pupils at many and remote locations become integrated into one classroom, each pupil retaining his direct contact with the teacher and incidentally, with the other pupils since, with this system, all pupils hear the question or response from any classroom.

Although intended primarily for transmitting questions and answers between pupils and studio teacher it has been shown that the system, while not of program quality, is practical for the teaching of music classes with the studio teacher being able to listen to the singing of any classroom.

Operation

The system consists of two studios with associated control rooms and eight schools, each school having from two to six classrooms equipped for educational television. Initially 32 classrooms are in the system but the consoles and control equipment provided will serve an ultimate of 36 classrooms. Any classroom may be connected to either studio so that two classes may be conducted simultaneously. Fig. 1 shows a block diagram of the entire system.

Before a class is scheduled to begin the program director selects the classrooms to be used. The cabinet in the equipment room as shown in Figs. 2, 3, and 4 has a rotary switch for each classroom. He sets each to one of the following positions: OFF, STUDIO A, STUDIO B, or EQUIPMENT ROOM.

In this latter position he may listen directly to the particular classroom, all others being undisturbed. If he fails to reach the classroom because of failure of that teacher to turn on her power switch, he advances the rotary switch momentarily to a RING position. In this position a buzzer sounds in the classroom which is the teacher's signal to turn on her power switch.

As the teaching of the class proceeds the talk-back system remains normally "dead." If a pupil has a question, the local teacher in that classroom presses a push button on her desk. This lights a lamp on the console in the studio and also in the associated control room. These lamps remain on until the instructor acknowledges the question by verbally inviting the question and pressing the push button illuminated by the lamp. A red bulls-eye lights in the classroom as an "on the air" signal and the pupil asks the question without leaving his seat. Not only do those in the studio and control room hear the question, but, the occupants of all other classrooms hear it as well. Of course, by operating

the same push button the instructor can listen to the classroom at any time and receive answers to posed questions. An important feature of the system is that operation and control remain completely with the studio except for the initial signaling of a question which does not disturb either the studio or other classrooms.

Transmission Design

The principal design requirement of this system was that any pupil should be able to talk, without leaving his seat, to the instructor in the studio and to be heard by all other pupils in classrooms connected to the system.

The closed-circuit video facilities could not be used for this talk-back feature since direction of feed would have to be instantaneously reversed and problems of signaling and centralized control seemed insurmountable. Commercially available intercommunication systems were considered unsuitable for several reasons:

1. Some of the associated schools would be located many miles apart and hence should utilize telephone circuits with the attendant limitation of approximately 6 milliwatts of signal power.
2. The desired signaling, control, and intercommunication functions should, for economic reasons, be done with not more than a single pair of wires per classroom.
3. The duplicate signal lamp and control functions desired were not available.
4. Co-ordination with the audio portion of the television circuit was required, to avoid acoustic feedback during talk-back periods.

During the development of this new system tests were made using broadcast-quality microphones, telephone-type carbon microphones, high-quality loudspeakers, and small low-cost loudspeakers as microphones, singly and in multiple. The combination of weak voices, reverberant rooms, and high noise level made it difficult to achieve sufficient intelligibility. Under these conditions microphones were no better than small loudspeakers and, with the necessary preamplifiers, were much more costly. Loudspeakers and power amplifiers would still be required for the receiving condition.

The final design uses two small loudspeakers suspended overhead near the front of the room directed slightly downward toward the rear of the room. A third loudspeaker is placed on the teacher's desk. These loudspeakers, shown in Fig. 5, serve as both microphones and loudspeakers using a reversible amplifier which was designed for the "School-to-Home" service whereby a disabled child at home listens and talks to his classroom.

Contrary to the popular quest for high fidelity and flat frequency response this amplifier has a response designed to peak in mid-band for maximum intelligibility under classroom conditions. The frequency characteristic of the amplifier is shown in Fig. 6 which also shows, for

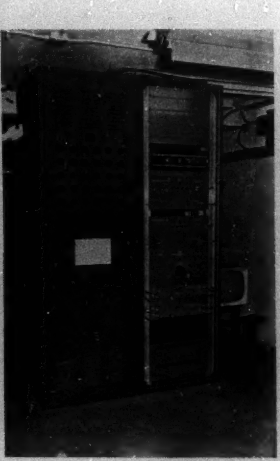

Fig. 2. Talk-back equipment cabinet on left and television equipment cabinet on right

Fig. 3. Control equipment and programing selector switches

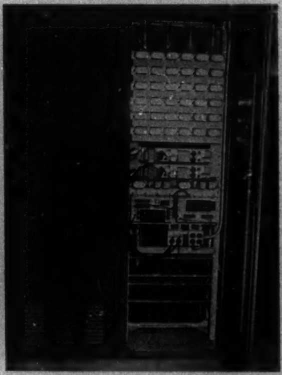

Fig. 4. Apparatus arrangement in equipment cabinet

Fig. 5. Installation arrangement in a typical classroom

comparison, the frequency characteristic of the common telephone which has evolved through the years as the best compromise between fidelity, intelligibility, and economics. The pass band of regular telephone message circuits is entirely adequate for this talk-back service thus avoiding the use of more costly "program" quality circuits such as are required for the best transmission of music.

Conventional intercommunication systems which use small loudspeakers as microphones are intended to provide 2-way talking circuits between two locations but usually one party or the other is close to his loudspeaker. The condition of a distant and, therefore, weak voice at one end attempting to talk to a person who is also distant from his loudspeaker is avoided automatically by the usual requirement that one party or the other "push-to-talk." The educational television talk-back system faces this problem in that a student in a distant corner of one classroom must be heard by a student in the distant corner of another classroom. The generally bare walls and floor which make the acoustics poor, the shuffling of papers, and the restlessness of school-age children all combine to make the transmission problem difficult. Multiple source origination, while generally to be avoided, becomes helpful under these conditions and since the same units are used as reproducers, a fairly uniform sound level is achieved throughout the room. A compressor-amplifier of the type frequently used in the radiobroadcast field assists greatly in overcoming the wide variation in volume between different children's voices and at various distances from the microphones. Levels are set with the amplifier operating in the middle of its range so that weak signals are expanded while strong signals are compressed, thus achieving automatic volume control.

The compressor-amplifier serves a dual purpose in that it is used to overcome the bridging loss of the many connected classrooms. A pad in its output circuit not only serves to make the level fed to the classrooms independent of the number of rooms connected, but also isolates each leg so that a trouble on any circuit will not disable the entire system. These pads can be so selected as to equalize the levels reaching schools located at various distances from the central bridging point. The pads affect only the outgoing level and differences in the incoming direction are absorbed by the compressor-amplifier.

At the school amplifiers normal sending levels range from +8 volume units for strong talkers down to the room noise level of −30 volume units. Within the city of Cortland the cable circuit loss ranges from 4 decibels for the nearest school to 10 decibels for the most distant. Transmission over a circuit longer than about 25 miles of loaded 19-gage cable would require telephone repeaters with due consideration being given to the simplexed control circuit. The relays in the control circuit impose a limit of 500 ohms for the simplex path or 2,000 ohms of conductor loop resistance which is equivalent to 23 miles of 19-gage loaded cable.

Equipment Design

In providing the equipment required for control, signaling, and switching many unusual design problems were encountered.

At the studio location the need was apparent for a console designed for complete simplicity of operation by the studio teacher or personnel in the control room. The desired features were instantaneous recognition of the schoolroom signal and immediate association with its control key, ease of operation, portability, appearance, and expansion. Various types of standard turrets and consoles were considered, but were found to lack one or more of the mechanical or other features desired. Three standard Western Electric 700-type turret cases as shown in Figs. 7 and 8 were combined for the console housing providing a good appearance and permitting ease of expansion since additional cases may be added as required. The illuminated type of push button normally used in the 6-button telephone set was found to be most desirable. These buttons embody the feature of direct illumination of the push button by an associated lamp and designation strips are provided as a part of the unit. A separate switch on the console permits talking back to the classrooms over this system if desired. A semiflexible cable was provided to facilitate movement about the studio.

In the equipment room a cabinet houses all the equipment required at the studio end. On the outside of the door affording desirable access to both the

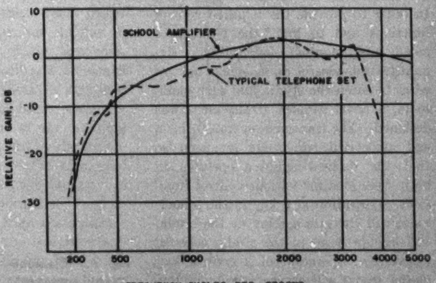

Fig. 6. Frequency response of classroom amplifier

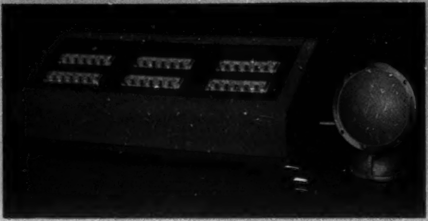

Fig. 7. Studio console

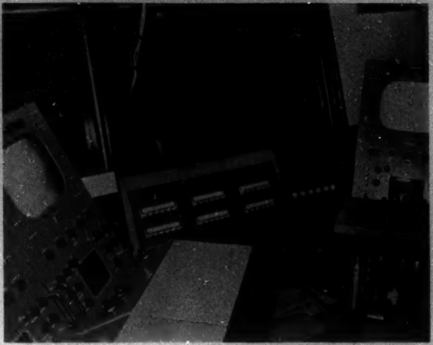

Fig. 8 (right). Control room console

program director and maintenance personnel, are mounted rotary-type switches. These switches connect the schoolroom circuits to the desired studio and provide required functions. Operational instructions and designations are also mounted on the door.

The low-voltage power requirements for this talk-back equipment at the studio are met by the new standard Western Electric *101-J* power plant. The console lamps use a 10-volt a-c supply with a maximum drain of 3 amperes and the relays require a 24-volt d-c supply with a maximum drain of 1.5 amperes. These requirements and provision for 50% growth are met by this power plant.

In the schoolroom all equipment was prewired and mounted on a backboard and then installed as a single unit as shown in Fig. 9. Power for the lamp and relays is provided by another new standard Western Electric power plant, the *101-H*. This is a small power plant which was designed for small key telephone systems. The output of this power plant is adequate for the schoolroom requirements.

The number of cable conductors required between the studio and classroom locations was of major importance. In order to provide the required control functions and to limit the number of conductors required for talking, signaling, and control to a single pair of wires between the studio and each classroom, a novel simplex arrangement was designed. The transmission transformers and associated relays are arranged so that the derived simplex operates in both directions for various control functions. Operation of a key in the schoolroom will energize a relay at the studio and light a lamp in the studio console. Conversely, operation of a control key in the studio will arrange the amplifiers at the studio and in the classroom for transmission and, in addition, light an "On the Air" lamp in the classroom.

The general over-all design features the use of standard Bell System equipment wherever practical. The maintenance personnel are familiar with this equipment and it is readily available from stock. Testing procedures will not require any special tools or equipment. Both of these items should expedite maintenance on the over-all system.

Selection and Operation

Selection of the classrooms to be associated with either of the studios is made by the program director at the equipment cabinet. Each schoolroom through its line circuit is associated with a rotary switch, *S2*, as shown in Fig. 10, that enables the schoolroom to be connected to either studio, the equipment room, or to be left disconnected from all locations. All classrooms to be associated with the studio program are selected prior to the start of program, according to the scheduled arrangement.

The teachers in the classrooms will operate the power switch associated with their equipment at program time. The operation of the power switch energizes the power plant which operates relay *B* disconnecting the schoolroom buzzer from the line. The power switch also energizes the schoolroom amplifier, and arranges its control equipment to function under control of the studio console over a simplex of the line circuit. The signaling key in the classroom will also operate over the simplex in the reverse direction. The speakers are normally on the output side of the schoolroom amplifier in the receive position.

Operation of the classroom rotary switch will connect its line circuit through to the output side of the bridging amplifier associated with the particular studio.

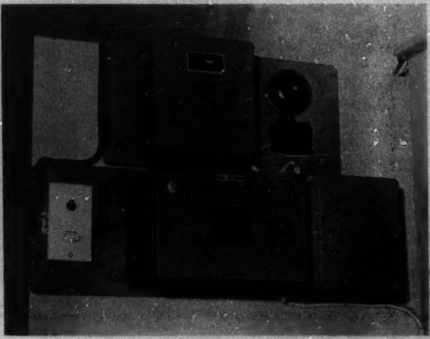

Fig. 9. Classroom control equipment

Vol.
Pt. 1
195

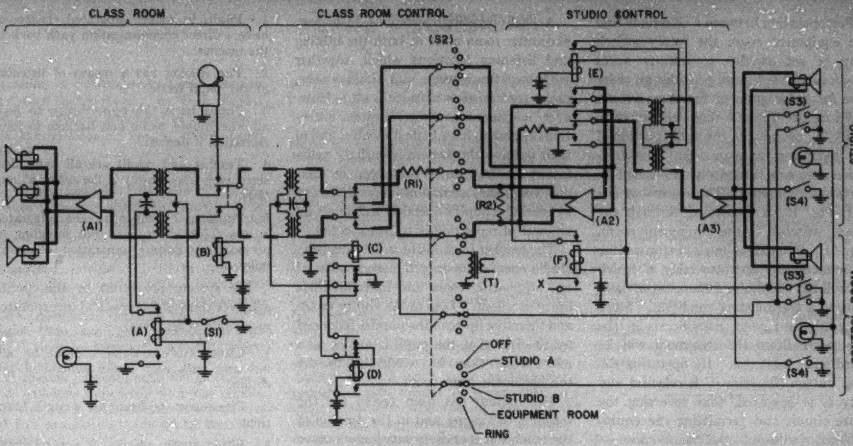

Fig. 10. System circuit

The rotary switch also connects the lamp and control leads of the schoolroom to the selected studio control consoles located in the studio and its control room. All schoolrooms associated with the particular program are selected in the same manner and consequently are all in the normal or receive position. The studio speakers are normally on the output terminals of the studio amplifier.

The studio line circuit is bridged to the schoolroom line circuits at the output terminals of the bridging amplifier. All stations therefore are normally in the listening position. A shunting arrangement is provided across the output of the bridging amplifier to prevent the classrooms from interrupting the studio during the silent periods. A muting arrangement on the television microphone is provided during the operate period to prevent acoustic feedback between the audio portion of the video network and the talk-back circuit.

During the progress of the lesson any associated schoolroom may indicate to the studio teacher that they wish to ask a question by momentarily operating the push button located on the teacher's desk. Operation of the push button will operate the *D* relay over the simplex of the line. The *D* relay will lock operated under control of its associated *C* relay and light its line lamp in the consoles in the studio and associated control room. The *A* relay in the schoolroom is also operated but performs no function at this time, transmission being prevented by the shunt on the output of the bridging amplifier. The schoolroom now awaits instruction from the studio teacher as the talk-back is completely under control of the studio. At the convenience of the studio teacher the schoolroom will be instructed over the television system to proceed with their question. The illuminated button in either the studio or control room console must now be operated, energizing the *C* relay which removes the shunt from the output terminal of the bridging amplifier and mutes the studio microphone. The operation of the *C* relay transfers the schoolroom line from the output to the input terminals of the bridging amplifier, removes the locking path to the *D* relay, extinguishes the line lamp, and grounds the simplex of the line circuit to operate the *A* relay in the schoolroom. The operation of the *A* relay lights the "On the Air" lamp in the schoolroom, and reverses the school amplifier which places the speakers on the input and the line on the output terminals of the amplifier. The classroom voices will now be picked up by the schoolroom speakers, amplified in the schoolroom amplifier, sent over the line to the imput of the bridging amplifier, and will be heard by the studio, control room, and all of the connected classrooms. Release of the button will restore the circuit to normal.

Audio transmission from the studio is normally carried over the television system; however, provision has been made that enables the studio teacher to talk over the talk-back circuit. A studio control key, *S4*, is provided at the consoles for this feature. Operation of the *S4* key operates the *E* relay which transfers the studio line circuit from the output to the input terminals of the *A2* amplifier. The *E* relay operates the *F* relay which removes the shunt from the output terminals of amplifier *A2* and mutes the studio microphone. The *E* relay also reverses the *A3* amplifier and places the speakers on the input and the bridging amplifier *A2* on the output terminals of the *A3* amplifier. The studio or control room may now talk to all connected classrooms.

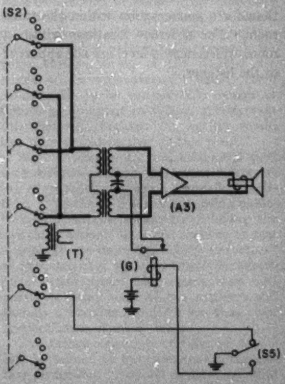

Fig. 11. Equipment room talk-back circuit

For operation between a classroom and the equipment room the rotary switch may be set at the EQUIPMENT ROOM position. This feature provides an order wire for preprogram or maintenance use and a means of monitoring a classroom to verify, by listening to the audio portion of the television program, that the television sets are turned on and tuned to the proper channel. The classroom circuit, Fig. 10, is connected through the rotary switches to the equipment room, Fig. 11. Ground at push-button switch *S5* immediately operates relay *C* which grounds the simplex and changes the classroom to a transmitting condition. Since the equipment room amplifier is in the receive condition the classroom will be heard and monitored. By operating the push button *S5*, relay *C* is released and relay *G* is operated, thus reversing the entire circuit and permitting the equipment room to talk to the classroom.

If a classroom teacher has failed to turn on her power switch, the studio will be unable to hear room noise from that room.

With the power switch off, relay *B* will be released, connecting the line to a buzzer. In the equipment room, operation of the *S2* rotary switch to the RING position will energize the buzzer and indicate to the classroom teacher that she should operate the power switch in her room.

Performance

Under test conditions a teacher can walk anywhere in the classroom and talk back and forth with a teacher anywhere in another classroom. When talking at a normal conversational voice level, intelligibility is satisfactory with requests for repetition being no more frequent than for a conversation within the same room. For different locations within a room, differences in level are not apparent to the listener.

Actual operating conditions, of course, encounter room noise at both the talking and listening locations which, together with sometimes weak and timid voices, make transmission more difficult. However, teachers accustomed to such conditions appear to have little difficulty, and in their opinion the system is entirely satisfactory. They know that even in their own room they sometimes have difficulty in hearing a pupil's question and a certain amount of repetition is to be expected.

The teacher back in the quiet television studio encounters only the room noise of the originating room and finds intelligibility excellent. Loss of the ability to see and therefore lip-read the pupil is balanced by the fact that the pupil is nearer to a microphone than he would be to the teacher in the same room.

The system has been tested for the teaching of singing and in the opinion of the teacher it is entirely satisfactory since she can instantly listen to any class and judge its pitch, timing, and performance of part singing.

The ability to switch from one room to another by the push of a button makes apparent the value of acoustic tile ceilings in reducing reverberations in the classrooms. About half of the classrooms have such ceilings and the improvement in intelligibility and naturalness from these rooms is very evident. Of course the acoustic ceiling is of great value to the teacher who teaches every day in that room and also improves the reproduction of recorded music used in music appreciation courses. The proof is most strikingly shown by the quick switch from classroom to classroom of the talk-back system.

Conclusions

This talk-back system is a valuable adjunct to an educational television system for several reasons:

1. Pupils in widely separated classrooms have a direct communication path back to the teacher.
2. The teacher has a means of listening to any pupil recite.
3. Pupils have the opportunity to hear all other pupils recite and partake in joint recitation if desired.
4. Teacher and pupils are all kept alert since each may question the other at any time.
5. Pupils and teacher become integrated into a joint effort with full mingling of personalities despite separation of many miles.

The system presented in this paper achieves these objectives and incorporates many salient features:

1. Classrooms can signal a desire to talk but may talk only under control of the studio.
2. Classrooms perform no control functions.
3. Either studio teacher or control room operator may assume control.
4. Individual classrooms may be split off from the system at any time for direct communication and for program readiness checks.
5. If classroom power switch is inadvertently in the OFF position the room may be called by a buzzer.
6. Only a single pair of wires is required from each classroom back to the studio.
7. Regular telephone circuits are used.
8. All components are standard unmodified items easily obtained if replacement is required.
9. The system can be expanded to care for additional schools and classrooms.

The most important criterion of any design is customer satisfaction. It need only be said that an experienced and critical customer is not only satisfied, but proud of the system just described, and believes that another step forward has been made in the quest for better methods of educating the youth of the nation.

LATE DISCUSSIONS

Discussion of "Organic-Moderated Reactors for Central Station Power," by W. E. Parkins and E. F. Weisner, published in Communication and Electronics, January 1959, pages 985–93.

A. C. Werden, Jr. (Southern California Edison Company, Glendale, Calif.): The paper under consideration discusses the organic-moderated reactor experiment (OMRE) conducted by the Atomics International Division of North American Aviation Inc., together with a description of their 12.5-emw (electrical megawatts) OMR, now being designed for the city of Piqua, Ohio, and their proposed 150-emw OMR plant for large central-station power plants.

It frankly presents both the advantages and problems associated with the organic fluids, which is the key factor in the successful and economical operation of the OMR concept.

The estimated cost figures presented in the paper, in the order of 18 and 10 mills per kilowatt-hour for small and large plants respectively, and which are based on a relatively short but highly encouraging operating experiment, appear to be conservatively reasonable and indicative of the justification for exploring the concept by constructing full-scale plants.

The results of the OMRE were somewhat unique in the history of power-reactor developments, in that the operating performance was in full accord with design specifications and was without unforeseen problems of significance. Undoubtedly, this was due in part to the compatibility of the organic with the materials of the fuel elements as well as with other conventional materials of construction.

The paper comments that an equilibrium polymer content up to 30% has been achieved and that the polymer formed at this concentration was $2^{1}/_{4}$ pounds per megawatt-hour. While total quantities of the organic are not given, it is presumed that $2^{1}/_{4}$ pounds per emw-hour make-up could result in a 100% replacement on an annual basis and is in support of achieving equilibrium over an extended period of time. Perhaps the authors would care to comment further on the expected performance of the organic over an extended period of time. This is very important since the estimated make-up now contributes 1 mill per electrical kilowatt-hour to the operating costs.

A second point the authors may wish to comment further on is the low steam pressure of 450 pounds per square inch. Since there is nothing inherent in the OMR design that prohibits the use of higher steam pressures, it would appear that in view of the steam temperature available, a higher pressure would produce a better heat rate and a higher thermal efficiency.

A third question of interest would be the expected consequences of a steam-generator failure whereby water might get into the primary loop.

Since the OMR for Piqua will utilize Santowax-R in place of Santowax-OM, and aluminum-clad fuel elements instead of stainless-steel cladding, a confirmation of the expected reduced rate of polymer formation, as predicted by reason of the reduced gamma exposure resulting from the lower fuel enrichment, will, no doubt, be a factor of interest in the operation at Piqua.

The load-change characteristics of the OMR operation at Piqua should also prove to be of interest. Although the controls will be designed to maintain constant steam pressure, they do appear to permit a temperature variation. Assuming the manufacturer's conservative loading schedule for steam turbines of 5% rated load per minute with constant temperature, it is apparent that with a temperature change of 75 degrees this load time could be increased appreciably.

In summary, the principal disadvantages of some instability of the organic under radiation coupled with poor heat-transfer properties with respect to water, this organic moderator and coolant enjoys impressive offsetting advantages in: 1. high-temperature capabilities at low pressure because of its low vapor pressure; 2. compatibility with fuel, canning, and structural materials resulting in low corrosion rates; 3. low induced radioactivity; and 4. no hazardous chemical reactions.

In addition to these characteristics either precluding the necessity for or substantially reducing the cost of external containment, it could conceivably result that this type of reactor plant would be acceptable closer to the load centers than would other types, with consequently reduced transmission cost and losses.

W. E. Parkins and E. F. Weisner: Since the paper was written, additional operating experience has been obtained on the OMRE. This reactor has operated for extended periods of time at 40% polymer content. There was a further decrease in the decomposition rate, and hence in the projected organic make-up costs, as expected. It now appears that for a power reactor of the Piqua type, in which slightly enriched uranium metal or oxide is used as fuel, that the organic make-up cost will be approximately 0.7 mill per electrical kilowatt-hour. This figure includes the effect of the absorption of gamma energy by the fuel itself, a point which the operation at Piqua will quantitatively establish.

The steam pressure of 450 pounds per square inch is used in the Piqua plant because all the installed boilers and turbines operate from a common steam header at this pressure. The nuclear reactor will supply steam to this header as do the other (conventional) boilers and the steam must therefore be produced at the same pressure. Organic-moderated reactors could be used to generate steam at much higher pressures if this is required.

The consequences of a steam-generator failure have been studied and devices have been provided to cope with such an event. A tube failure will cause a pressure increase on the organic side which will be relieved through two rupture-disk relief valves. The fluid discharged will be condensed and contained in the reactor drain tank. Operation of a pressure-relief valve will also provide a signal which shuts the reactor down and relieves the pressure on the steam side of the steam generator. Small water leaks in the steam generator can be tolerated since the degasifier provided to remove the radiolytic gases formed, will simultaneously remove any water present in the organic.

The reactor steam-generating complex will be operated to produce constant-pressure steam and also constant-temperature steam over a load range of 15% to 100% of full power. The rate of load change with this plant can be as rapid as with a conventional plant, being limited by the turbine in either case.

We wish to thank Mr. Werden for his comments on this paper and his appreciation of the problems of nuclear-reactor power plants.

◆

Discussion of "The Controlled Rectifier: Key to the Continuing Control Renaissance," by J. D. Harnden, Jr., published in Communication and Electronics, January 1959, pages 1006–12.

I. K. Dortort (I-T-E Circuit Breaker Company, Philadelphia, Pa.): In arriving at some estimate of the efficiency of equipments using the controlled rectifier *ZJ-39A*, the author points out that the forward drop is but one volt out of a peak voltage rating of 400. We assume the peak voltage rating is equivalent to the peak inverse voltage rating of power diodes, in which case it is expected that the recommended rms alternating voltage to be applied to these rectifiers would not be much over 115 volts. Even at this reduced voltage, the efficiency is still excellent. However, the author's statement raises the question of recommended peak operating voltage, a question which is further emphasized by the statement that it is possible to use these devices in a control system in which forward conduction is initiated by exceeding the "breakover" voltage instead of a signal on the control electrode. Since the forward breakover voltage and the peak inverse voltage rating of the rectifier are stated to be approximately equal, there would seem to be considerable danger of failure in applying controlled rectifiers in this manner. Perhaps the author would like to comment further on this point.

We are puzzled by the statement that time delay is necessary between the triggering of parallel connected controlled rectifiers. Mention is made of equalizing inductors as a suitable means for delaying the switching action. It would seem more reasonable to use these "equalizing inductors" as they are used with electronic devices to force simultaneous firing rather than purposely to delay some of the rectifiers and thereby cause them to carry less than their proportionate share of load.

The bridge-connected rectifier of Fig. 2 (H) is claimed to have inherent commutation protection. I do not understand what is meant here and would appreciate the author's explanation.

T. Bernstein (University of Wisconsin, Madison, Wis.): The literature dealing with controlled rectifiers emphasizes the fact that the gate circuit loses control after firing. The author mentions that there is a possibility that the controlled rectifier can be turned off by gate action. Have such units been made? What would be the magnitude of the gate signal necessary to turn off the rectifier as compared to the signal necessary to turn it on? Since the controlled rectifiers presently available are not designed for reverse voltage on the gate junction, I am in doubt as to whether the turn-off gate voltage would be a reversed polarity gate signal. This information will be useful as an indication of the future potentialities of the controlled rectifier.

◆

Discussion of "Magnet Wire for 600 C Temperature Transfers," by W. W. Wareham, published in Communication and Electronics, March 1959, pages 66–70.

Marvin M. Klein (Kollsman Instrument Corporation, Elmhurst, N. Y.): Mr. Wareham's paper is extremely interesting in view of some parallel problems which have been investigated here. We have been engaged in the development of rotating transducers for use at ultrahigh temperatures for the last year and a half. At that time the use of nickel-clad copper wire was considered and rejected for the following reasons:

1. An examination of the equilibrium diagram of nickel and copper indicates the existence of a continuous group of stable solid solutions from zero % of one of the elements to 100% of the element.

2. Inter-diffusion rates between atoms of the plate metal and that of the substrate metal are negligible at room temperatures. However, as is well known in kinetic theory, atomic or molecular motilities increase rapidly with temperature. Thus, at the 600 C temperatures referred to in the paper being discussed, the alloying process would take place in finite, appreciable time. Furthermore, the entropy of the process would indicate that the process would be complete only when the plate would be completely destroyed, and when a uniform composition would exist throughout the wire.

3. In general, alloying, whether due to substitutional solid solutions, interstitial solid solutions, or to intermetallic compounds, tends to increase the electrical resistance. This is understandable, if one considers the so-called "Free Electron" theory of solid conductors. In this theory the bond energies between the nuclei of the atoms making up the crystalline lattice structure, and some of the outer planetary electrons are low. Thus so-called free electrons are continuously migrating back and forth, as energy bonds are continuously being broken and reformed. It is the distribution of these free electrons which determines the comparative conductivity of the material. The introduction of any foreign atoms into a conductor's lattice structure usually distorts the lattice parameters enough to restrict the free electron motility. Thus, the resistance is permanently increased.

From the points brought out earlier in this discussion the resistance must continuously and irreversibly increase with time and temperature.

As a result of this line of thinking, we dropped the idea of using nickel-plated copper from further consideration, and decided to concentrate on finding some organization that would satisfactorily coat pure silver with ceramic or glass for us.

In further agreement with our thinking, a nearby manufacturer of fine wire reported the following to us some months ago:

He had coated fine silver wire with a light plating of aluminum and had then anodized the aluminum, thus securing a high conductive silver wire with a good ultrahigh temperature coating. Unfortunately, the diffusion affect at high temperatures and the consequent increase in resistance led to the dropping of this wire, at least in the fine sizes.

It might be added in conclusion that the "skin-effect" phenomenon makes this permanent increase of resistance particularly serious in the windings of transformers to be used for pulse transmission. In such applications rather serious degradation of leading edge might be expected.

Digital Computer Design of Pulse Transformers

P. E. LEGO
ASSOCIATE MEMBER AIEE

R. L. GREENE
ASSOCIATE MEMBER AIEE

J. M. BANIC, JR.
NONMEMBER AIEE

THE DEVELOPMENT of pulsed radar created a need for a relatively new type of transformer, one that transforms the energy in a pulse with an approximately rectangular shape and a time duration in the order of microseconds.[1] A good deal of experimental work has been done in this field, which has evolved a trial and error method of designing pulse transformers.[1-3] This method is tedious and time consuming since it involves the use of many interdependent mathematical calculations and the necessity of making these same calculations over and over again before a satisfactory design is obtained.

Different people have attempted to reduce the labor involved in the trial and error method through the use of nomograms and empirical charts prepared from past designs.[4] Although the nomogram approach to the trial and error method has helped reduce the number of trial calculations in the design procedure, pulse transformer designing still has required a disproportionate amount of calculations.

The availability of digital computers and their use in the solution of similar transformer design problems[5,6] suggested an investigation into the feasibility of utilizing digital computers to design pulse transformers.

The first problem was to choose a design method for programming the computer. There were at least three approaches to this problem: first, to use the customary trial and error method of the design engineer; second, to use the nomogram form of design procedure and reduce the nomograms to mathematical equations; and third, to try a completely new approach to the design problem. The decision was made to program the trial and error method of the design engineer. This method was chosen in order to utilize a proved technique with a minimum of programming and provide usable results in the immediate future. Incorporating the nomograms into the program would have reduced the number of iterations performed by the computer, but at the expense of more complex programming. The basic trial and error program would still have been required in either case, since the nomogram method is not complete in itself. A new design procedure would have delayed the program for an indefinite period of time, and was not economically feasible.

Since the specification information required for a pulse transformer is covered in Electronics Industries Association Standard *RS176*,[7] this was adopted as the major part of the input data to the computer.

In addition, it was felt that the input data should include information for setting the allowable tolerances on the electrical parameters required by the customer specifications.

Design Philosophy

The output of a typical pulse transformer resembles the waveform shown in Fig. 1. The objective of the transformer designer is to obtain a specified level of surge impedance while maintaining the rise time, fall time, and droop within guaranteed temperature rise. The trial and error method of design is the usual way of attaining these goals and tailoring the design for minimum size, weight, and economical manufacturing. This method involves assuming certain materials and configurations, and using recommended working stresses for safe practice under these conditions, calculating the performance parameters that can be realized. Comparing these parameters with those required to meet the customers' specifications reveals which, if any, of the initial assumptions must be modified to more nearly match these quantities. This process is continued until all the specifications are met, or until it can be demonstrated that the design requirements are contradictory and, therefore, impossible to attain.

In attempting to program the trial and error design method into the computer, a complete mathematical outline of the procedure was prepared along with a block diagram showing the necessary design steps. This block diagram is referred to as a flow diagram, since it shows the actual flow of information and decisions through the computer.

Initial Procedure

With the problem in an elementary flow diagram form, the next step was to adapt certain of the trial and error design procedures to computer usage.

1. The first step was to detail the input information necessary to produce a completed design. It was thought that the program should be self contained, or continuous, since intermediate observation of data is time consuming and costly.

2. The computer makes best use of information in mathematical equation form. Therefore all the data, whenever possible, were reduced to this form. Such data as standard parts had to be retained in tabular form. These data were reduced to a minimum and placed in the stored data area of the computer.

3. In order to have a foundation on which to base the program, certain assumptions have to be made such as the choice of working values for magnetic flux density, current density, and other factors which can be based on power or voltage levels.

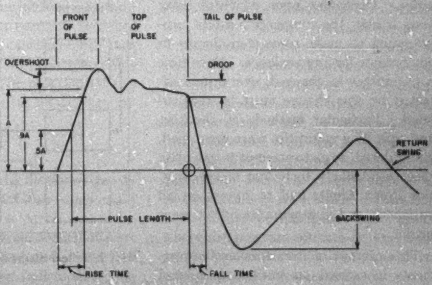

Fig. 1. Typical transformer output pulse. A is the nominal amplitude of the pulse

Paper 59-48, recommended by the AIEE Computing Devices and Electronics Committees and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1-6, 1959. Manuscript submitted June 27, 1958; made available for printing November 21, 1958.

P. E. Lego, R. L. Greene, and J. M. Banic, Jr. are with the Westinghouse Electric Corporation; Mr. Lego is at East Pittsburgh, Pa., and Mr. Greene and Mr. Banic are at Greenville, Pa.

4. It is desirable to choose the proper winding scheme with which to begin the design. There are a number of such schemes that can be used by the computer in designing a pulse transformer. The winding schemes in the computer program are sufficient to handle most of the requirements desired by the customer. Each of these schemes has the lowest leakage inductance and capacitance product for a given volume of coil to insure good high-frequency response. The configurations differ in the range of surge impedances that can be realized, the preponderance of secondary current caused by bifilar heater power, the transformer turns ratios that are practical, and the polarity of the output voltage with respect to the input. The input data specifies the sequence of winding schemes which are used by the computer. If the surge impedance cannot be brought within specification using a particular scheme, the computer will automatically select a new scheme and begin a redesign. This process continues until the surge impedance is matched, or until all the winding schemes have been tried. The computer will automatically halt in the latter instance. However, the information which the computer has calculated to this point will be printed out. This essentially gives a family of designs which may be used at the designer's discretion.

5. The key parameter that generates a family of designs, clustered about the required performance, is the number of turns in the coil. The initial trial value is obtained from a turns-index formula. This value is altered on successive iterations, when necessary, to meet the performance specifications.

6. The design engineer usually possesses the ability to make a certain amount of intuitive corrections while designing a transformer. He can examine some particular quantity which he had calculated, and through past experience, realize that this value is out of line. Or, he can project his thinking to future calculations and foresee that the design is going to fail in some respect. It is extremely difficult to program these engineering abilities into the computer. The machine can make only logical, yes or no, type decisions. It is therefore necessary to categorize every check that is made, on any calculation, into a logical type operation.

A quantity is either greater than, equal to, or less than a specified guarantee. Depending upon which of these tests is met, the computer must be programmed to make some step change to compensate for any variance. Each time a parameter is changed, every item affected by this change must be recalculated. Particular methods of checking and matching quantities were developed, and ordered, so as to attempt to calculate those most likely to be out of specification first. Limits had to be set on all variances and compensations that were made.

This process of iterations and adjustments is carried on until a completed design is obtained. The information obtained on the intermediate designs is also retained by printing it on magnetic tape before beginning a new iteration.

The initial outline and flow diagram were continually tested by hand calculating sample transformer designs. Corrections and additions were made where necessary. Out of this procedure evolved the completed flow diagram shown on Fig. 2.

Computer Program

Having drafted the final flow diagram, the next step was to program a digital computer to perform the necessary calculations. The IBM (International Business Machine Corporation) *704* digital computer was chosen for this project because of its availability and also because a large internally stored computer was desired.

This computer has three modes of information storage. These are: magnetic-core storage, magnetic-drum storage, and magnetic-tape storage. The magnetic-core storage is the primary storage unit of the computer and can retain information indefinitely. Information can be recalled from this type of storage in a few millionths of a second. Only information stored in this area can be directly used for calculation by the computer. The magnetic tapes supply the means for storing large quantities of information until it is needed. It must then be brought into the magnetic-core storage area for direct usage. Of these three modes, only magnetic-core and magnetic-tape storage were used in programming the pulse transformer design.

PROGRAM FORMULATION

The program was written completely in the computer's own language and introduced into the calculator by key punched instructions on standard IBM cards. The magnetic-core storage was not large enough to hold all the data and instructions necessary to cause an uninterrupted solution to this problem. For this reason, the program was divided into five phases. These phases are

1. An input routine which has the major function of loading data peculiar to each particular transformer solution into the calculator. In addition, this portion of the program contains all of the data used in common by the other sections. This data is comprised of such items as numerical constants, SHARE subroutines for finding square roots, natural logarithms, and exponentials, and other information such as wire tables and insulation thicknesses.

2. The major calculating routine contains all of the calculations normally performed in obtaining a transformer design, except those needed for finding transformer response.

3. The performance calculating routine, which finds such factors as rise time, fall time, droop, and overshoot by solving the differential equations generated by the transformer equivalent circuit. All of the operations needed to obtain complete performance data for the problem are performed here.

4. The output routine, which prints out all of the information calculated while the computer is iterating to a finished design. This routine prints out the response data needed to obtain a plot of the output pulse. It also prints out all of the transformer parameters as well as information on losses, efficiency, copper weights, and other pertinent data.

5. A master routine which controls all of the other routines and dictates the complete design process. It is this routine which contains the instructions needed to bring in the other routines from tape at the correct time. Each of the preceding phases was developed separately. The calculating routine and the transformer response sections were completed first. The input and output routines were written next; and the master routine last. Except for the master routine, all of

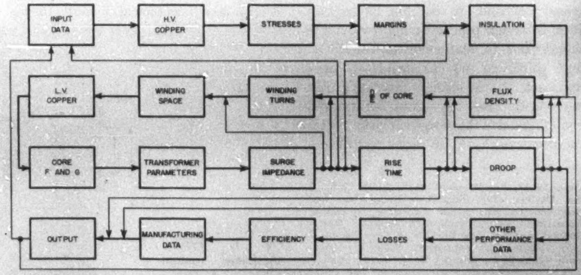

Fig. 2. Flow diagram. D and E are the core area proportions. F and G are the core window proportions

the preceding phases are stored on a single magnetic tape called the program tape. The master routine is stored on ten punched IBM cards. The specification input data needed for each transformer design is also punched onto IBM cards.

To execute a design, the master routine deck is read into the calculator by means of a card reader. The input data cards are placed in the card-reader hopper. The master routine then takes complete control of the proceedings. It first brings the input routine into magnetic-core storage from the program tape. The input routine causes the data cards to be read from the card hopper and placed in core storage. It also brings the stored data necessary for the design into core storage and returns the program control to the master routine. The master routine then manipulates the program tape in such a manner as to have the proper routine in core storage at the proper time. This process is continued until a finished design is reached. When a design is completed, the master routine will once again bring the input routine into core storage. The input routine will sense the card reader and attempt to read a new set of data cards. If there are more data cards present, another design will be initiated. If there are no more data cards in the hopper, then the computer will automatically halt.

Debugging

The debugging, or removing of errors from the program, was performed in stages. Each of the individual routines was tested separately using the data obtained while hand testing the flow diagrams. This procedure was used to ensure that the mathematical outline was being followed correctly. Also, it served as a check on the flow pattern of the routines. Once the individual routines had been successfully tested, the master program was written. This was the link needed to tie the individual sections together and enabled testing to start on the over-all program. Computer design of pulse transformers, which had already been hand designed, were attempted next. This procedure checked the program for logical correctness and allowed program changes to be made in order to improve the transformer design. During the debugging phase, the individual routines were stored on punched cards to facilitate the correction of errors. The entire program was placed on magnetic tape after the debugging process was completed. The master routine also handles this function. At the present, any new program changes required are inserted into the punched card deck and a new program tape is written.

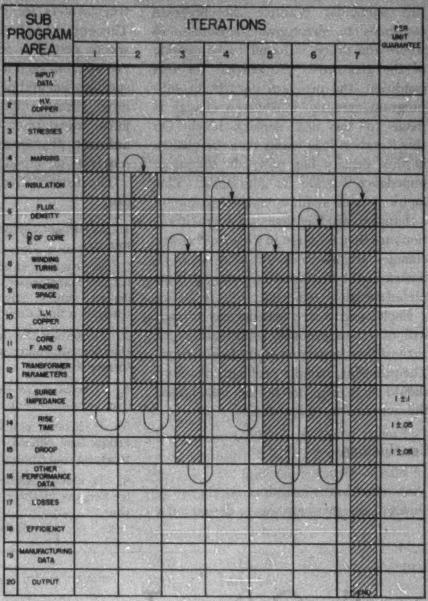

Fig. 3. Sample problem

The Completed Program

The final form of the program contains a total of over 7,000 machine instructions and 500 pieces of stored data. All of this information is stored on a single magnetic tape, except for the master program which is punched on ten standard IBM cards. The program is completely self contained in that once the design process is started, it continues without intervention until a completed transformer design is obtained.

To run a design it is only necessary to read the master routine into the calculator and place input data cards in the card reader hopper. The calculator will then complete the design and print the results on magnetic tape. The program takes a few minutes to complete an average design.

Sample Design

The sample problem displayed graphically in Fig. 3 shows the flow which might occur in designing a particular transformer. The subprogram areas shown are the same as those displayed in the flow diagram. It might be well to state that these areas are not completely inclusive and it is possible that iterations may be required within a subprogram to produce the desired results. The flow for this problem proceeds directly to area no. 13. Here, the computer checks the calculated surge impedance against the guarantee. The calculated value is found to be outside of the guarantee range and some type of compensation is required to correct for this variance. From the flow diagram of Fig. 2, we see that there are several paths which the computer can take from this point. The path chosen depends on whether the surge impedance is below, or above, the guarantee and also upon how great the deviation is. The path shown in the sample problem is that which would be taken if the surge impedance were lower than the guarantee but within a specified percentage of the guarantee. The program here retraces to subprogram area no. 5 where the insulation thickness would be adjusted by a ratio calculated from the magnitudes of the calculated surge impedance and its guarantee. Here, the program iterates to subprogram area no. 8 where the winding turns would be changed. Once again, where the program retraces to, and what particular compensation is used, is determined by tests which are made on the calculated values and the guarantee. For this particular example the program continues to subprogram area no. 15 where the droop is found to be outside of the guarantee. To correct for this condition, the program iterates to subprogram area no. 6 where a change is made in the flux density level. On this iteration it is found that the change in flux density has now put the surge impedance outside its guarantee. This factor is once again compensated for by a change in winding turns. Several iterations are then required in which successive changes are made in the ratio of D to E and in the flux density, before a completed design is achieved.

Each particular transformer design will, of course, probably follow a different path of flow in getting to its final design. The preceding sample problem, however, should help one to better understand the complexities of any design.

Conclusions

As stated in the introduction, the initial object of this program was to design pulse transformers using a digital computer. This object has been met and in most respects surpasses what was initially expected from such a program. With only specification and performance data for an input, the computer completely designs a pulse transformer. This design is done automatically in a continuous process, requiring no outside monitoring.

The distinct advantages of the program are:

1. It reduces the design time from days to minutes.
2. It provides, in addition to a final design for the transformer, all of the intermediate design values calculated while iterating towards a final design.
3. It enables the design engineer to study the effects of parameter variation on transformer design.
4. It releases the design engineer from the drudgery of routine calculations.
5. It insures consistency of design procedure and should allow the manufacturer to give rapid quotes on proposed designs.
6. It should allow faster delivery service because of the reduction in engineering time.

The Optimum Transmission-Line Pulse Transformer

F. J. YOUNG

E. R. SCHATZ
MEMBER AIEE

J. B. WOODFORD
ASSOCIATE MEMBER AIEE

TAPERED transmission lines have been found to be useful for pulse-transformer service.[1,2] It is the object of this paper to develop a new theory for the optimization of the taper which is based upon the transient rather than the steady-state response of the transmission-line pulse transformer. A criterion for the optimum taper will be established and then applied in a special case in which both ends of the line are nominally matched. Finally, the case of general terminations at both the input and output will be discussed.

There have been numerous analyses of the optimum taper based on the steady-state response of the tapered transmission-line pulse transformer. For instance, Bolinder establishes a Fourier transform method for the approximate calculation of a quantity defined as a reflection coefficient which has the same mathematical form as the reflection coefficient commonly defined for a uniform line. Optimum tapers are sometimes found by minimizing this reflection coefficient.[3] Lewis and Wells present expressions for both Bolinder's and a conventional reflection coefficient which are the same under certain conditions.[4] Bolinder's theory is not very useful for transient analyses because it does not fully consider the influence of the terminations and is based upon steady-state considerations. However, when the internal impedance of the sending-end signal generator equals the complex conjugate of the nominal sending-end impedance, Bolinder's reflection coefficient (evaluated at the sending end) takes on a physical meaning. It is a direct measure of how well the signal generator is matched to the sending end of the loaded line.

Many later works published in this field have been devoted to finding tapers which would minimize Bolinder's reflection coefficient over various ranges of frequency.[5–8] Physically, minimization of this coefficient results in maximum power being accepted by the input end of the tapered transmission line. For steady-state use, this is sufficient to guarantee maximum power at the load because all power which is put into the line eventually arrives at the load if the line is without loss. However, for pulse work it is necessary that the input power arrives at the load when it is needed, rather than at some later time. If some portion of the spectrum of input power is allowed to pass through the line more quickly than another portion, severe distortion may result in load voltage. Fidelity of pulse response is, of course, a criterion for optimization. Because the minimization of Bolinder's reflection coefficient does not necessarily insure a good reproduction of the input waveform at the output of a line, such a procedure does not yield the best taper

for a transmission-line pulse transformer.

The new theory developed here requires an accurate, usable transient solution for tapered transmission lines. Such a solution for all lines having a constant velocity of propagation has been derived in a companion paper.[9]

Initial Slope Criterion

The initial slope criterion was used by Kukel for judging the performance of various types of exponential-line pulse transformers. This criterion is a direct measure of how much distortion a short pulse will suffer when transformed in amplitude by a tapered line.[10] For example, let the transient responses sketched in Fig. 1 be the results of applying equal-step voltages to two equal-length lines having the same velocity of propagation, ratio of impedance transformation, nominal input and output impedances and terminations, but obeying different taper laws. The dotted curves are the responses of the lines to a pulse of length τ. It is apparent that line II distorts pulses more than line I. This is so because the magnitude of the initial slope

$$\left.\frac{dV}{dt}\right|_{t=\frac{L}{c}}$$

of the step response of line II is greater than that of line I. Thus the initial slope criterion can be stated as follows. In the case of lines having the same electrical length, the same ratio of impedance transformation, the same input and output nominal impedances, the same terminations, the best line for transforming pulses, which are short compared to the time it takes the step function response of that line to approach its final value, is that line which has the smallest magnitude of intial slope of the response to an exciting step function.

Derivation of the Optimum Line When Both Ends of the Line Are Nominally Matched

The initial slope μ of the output of a tapered line in finite difference form is

$$\left.\frac{V_{t+\Delta t}-V_t}{\Delta t}\right|_{t=L/c}$$

The quantity Δt can be chosen for convenience. Let $\Delta t=2L/cn$ where n is the number of elementary steps in the line. By equation 8 of the previous paper[9] $V(L/c)=K$ and $V(L/c+2L/cn)=K(1-m_1)$.

Then

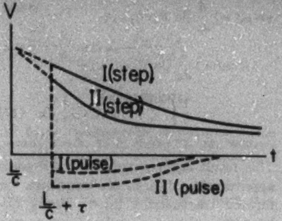

Fig. 1. Typical responses of a tapered transmission line to a step and a pulse

$$|\mu|=\left|\frac{cnm_1K}{2L}\right| \tag{1}$$

In the Appendix it can be seen that

$$m_1=\sum_{j=1}^{n-2}\rho_j\rho_{j+1}$$

for lines which are nominally matched at both ends. It is also shown in the Appendix that for large values of n

$$\sum_{j=1}^{n-2}\rho_j\rho_{j+1}=\frac{1}{4n}\int_0^L\left\{\frac{d}{dx}\,[\ln R(x)]\right\}^2dx \tag{2}$$

Substitution of equation 2 into equation 1 yields

$$|\mu|=\left|\frac{cK}{8L}\int_0^L\left\{\frac{d}{dx}\,[\ln R(x)]\right\}^2dx\right| \tag{3}$$

Because c, K, and L are constants the only quantity which can be adjusted to minimize $|\mu|$ is the taper function $R(x)$. The function $R(x)$ which makes the integral I a minimum must be determined. This will be done by the methods of the Calculus of Variations.[11,12]

Let

$$2I=\int_0^L\left\{\frac{d}{dx}\,[\ln R(x)]\right\}^2dx$$

and $R(x)=y+\alpha n(x)$ where $n(x)$ is any function such that $n(0)=n(L)=0$. Then

$$2I(\alpha)=\int_0^L\left\{\frac{d}{dx}[\ln(y+\alpha n[x])]\right\}^2dx \tag{4}$$

Differentiating $I(\alpha)$ with respect to α yields

$$I'(\alpha)=\int_0^L\left\{\frac{d}{dx}[\ln(y+\alpha n[x])]\right\}\times\left\{\frac{d}{dx}\left[\frac{n[x]}{y+\alpha n[x]}\right]\right\}dx \tag{5}$$

It can be seen that

$$I'(0)=\int_0^L\left\{\frac{d}{dx}\,[\ln y]\right\}\left\{\frac{d}{dx}\left[\frac{n(x)}{y}\right]\right\}dx \tag{6}$$

This expression can be integrated by parts. Let $U=d/dx(\ln\ y)$ and $dV=d/dx[n(x)/y]$.

From integration by parts

$$I'(0)=\left.\frac{n(x)}{y}\,\frac{d}{dx}(\ln y)\right|_0^L-\int_0^L\left[\frac{n(x)}{y}\,\frac{d^2}{dx^2}(\ln y)\right]dx \tag{7}$$

But by definition $n(0)=n(L)=0$. Under this condition equation 7 becomes

$$I'(0)=-\int_0^L\left[\frac{n(x)}{y}\,\frac{d^2}{dx^2}\,(\ln y)\right]dx \tag{8}$$

In order to find the function y which makes $I(0)$ an extremum, $I'(0)$ must be set equal to zero. For this to be true the integrand of equation 8 must equal zero. Because of the nature of the functions involved, the integrand is zero only if

$$\frac{d^2}{dx^2}(\ln y)=0 \tag{9}$$

The solution to this equation is given by $y=\exp(cx+b)$. But because $\alpha=0$, $R(x)=y$. To find the constants c and b the boundary conditions at $x=0$ and $x=L$ must be used. Upon the evaluation of c and b, $R(x)$ becomes

$$\frac{R(x)}{R(0)}=\exp\left\{\frac{x}{L}\left[\ln\frac{R(L)}{R(0)}\right]\right\} \tag{10}$$

Thus, for the case of a line nominally matched at both ends, the optimum taper is exponential. This is not too surprising in view of the results obtained in the previous paper.

The Optimum Line in General

The most general case that can be considered by the theory developed in this paper is that of finding the optimum tapered line in terms of its terminations. For this case an expression for the voltage response of a line with arbitarary terminations must be derived. Equation 20 of the appendix gives the most general form of m_1. The quantities ρ_n and ρ_0 are functions of the terminations and ρ_j is defined in the Appendix. When n gets large the quantities ρ_j become proportional to the logarithmic derivative of the surge resistance function $R(x)$. For large values of n, m_1 is given by

$$m_1=\frac{\rho_nd}{2ndx}[\ln\ R(x)]_{x=0}+\frac{\rho_0d}{2ndx}[\ln R(x)]_{x=L}+\frac{1}{4n}\int_0^L\left\{\frac{d}{dx}[\ln\ R(x)]\right\}^2dx \tag{11}$$

Substitution of m_1 into equation 2 of the previous paper yields the response of the line after much algebraic manipulation.

$$V(s,L)=\frac{\frac{1}{2}V_g(s)\epsilon^{-sL/c}\frac{2R_n}{R_n+Z_g}\frac{2Z_L}{R_1+Z_L}\prod_{j=1}^{n-1}\frac{2R_j}{R_j+R_{j+1}}}{1+\frac{1}{2n}\left\{\rho_n(s)\frac{d}{dx}[\ln R(x)]_{x=0}+\rho_0(s)\frac{d}{dx}[\ln R(x)]_{x=L}+\frac{1}{2}\int_0^L\left[\frac{d}{dx}\ln R(x)\right]^2dx\right\}\epsilon^{-2sL/nc}+\ldots} \tag{12}$$

Let

$$V_g(s)=\frac{e_g}{s}\text{ and }K=2e_g\prod_{j=1}^{n-1}\frac{2R_j}{R_j+R_{j+1}}$$

Then by division

$$\frac{V(s,L)}{K}=\frac{R_nZ_L(s)\epsilon^{-sL/c}}{s[R_n+Z_g(s)][R_1+Z_L(s)]}\times\left(1-\frac{\epsilon^{-2sL/cn}}{2n}\left\{\rho_n(s)\frac{d}{dx}[\ln R(x)]_{x=0}+\rho_0(s)\frac{d}{dx}[\ln R(x)]_{x=L}+\frac{1}{2}\int_0^L\left[\frac{d}{dx}\ln R(x)\right]^2dx\right\}+\right) \tag{13}$$

Equation 13 is the Laplace transform of the output of a tapered line with taper function $R(x)$ terminated at the input with an impedance $Z_g(s)$ and at the output with $Z_L(s)$. By the initial value theorem of Laplace transform theory

$$V\left(\frac{L}{c},L\right)=\frac{KR_nZ_L(\infty)}{[R_n+Z_g(\infty)][R_1+Z_L(\infty)]} \tag{14}$$

$$V\left\{t=\frac{L}{c}\left[1+\frac{2}{n}\right],L\right\}\cong\mathcal{L}^{-1}\left\{\frac{KR_nZ_L(s)\epsilon^{-sL/c}}{s[R_n+Z_g(s)][R_1+Z_L(s)]}\right\}\Bigg|_{t=L/c(1+2/n)}-\frac{KR_nZ_L(\infty)\left\{\rho_n(\infty)\frac{d}{dx}[\ln R(x)]_{x=0}+\rho_0(\infty)\frac{d}{dx}[\ln R(x)]_{x=L}+\frac{1}{2}\int_0^L\left[\frac{d}{dx}\ln R(x)\right]^2dx\right\}+\ldots}{2n[R_n+Z_g(\infty)][R_1+ZL(\infty)]} \tag{15}$$

If n is large the first term of equation 15 will be almost equal to the quantity $V(L/c,L)$ given by equation 14. By substituting equations 14 and 15 into equation 1 the initial slope can be determined. It is given by

$$\mu=\frac{cnm_1V\left(\frac{L}{c},L\right)}{2L} \tag{16}$$

Given the terminations, the length of line, and the nominal impedances at each end, the taper function $R(x)$ which is optimum, can be found by determining the $R(x)$ which minimizes the magnitude of the initial slope μ. To minimize the initial slope, the function ϕ must be minimized. The function ϕ is given by

$$\phi=\rho_n(\infty)\frac{d}{dx}[\ln R(x)]_{x=0}+\rho_0(\infty)\frac{d}{dx}[\ln R(x)]_{x=L}+\frac{1}{2}\int_0^L\left\{\frac{a}{dx}[\ln R(x)]\right\}^2dx \tag{17}$$

This result is given support by Frank's approximate theory of transients on tapered transmission lines. Frank obtains the distortion suffered by a step function which has been transformed by a tapered line which is nominally matched at the load end.[13] The problem of minimizing Frank's distortion is identical to that of minimizing ϕ when $\rho_0(\infty)=0$. Frank's theory is valid for values of time very close to $t=L/c$ only.

The authors have not succeeded in obtaining an analytical solution for the $R(x)$ function in terms of the terminations which yields a minimum value of ϕ. Actually for some capacitative terminations the initial slope may have no minimum value and may take on positive values. However, equation 17 is of some computational value. For given terminations, various known tapers can be substituted into equation 17 to obtain the line with the most desirable initial slope.

Equation 16 is of value in another way. For appropriately short pulses the initial value of the output voltage from equation 14 and the initial slope from equation 16 may give enough of the response curve to analyze a line with given terminations and taper function.

Conclusions

The initial slope criterion is useful only during the interval of time that the step response falls off linearly with its initial slope. After this interval of time the initial slope criterion fails to yield any information about the transient response. By the initial slope criterion the lines considered in the previous paper in Fig. 5 are ordered from best to worst as follows: parabolic, hyperbolic, exponential, and Bessel. This choice remains valid until about $ct/L=1.1$. For pulses longer than that but shorter than $1.6L/c$ they are ordered from best to worst as follows: hyperbolic, exponential, parabolic, and Bessel. For still longer pulse lengths the order is different. Thus, it can be seen that the initial slope criterion must be used only in conjunction with the total transient response and with certain pulse lengths in mind. Clearly, if the initial slope criterion is used alone erroneous judgement of lines can occur. For example, if one wished to transform pulses of duration of 1.5 L/c seconds with one of the lines mentioned in Fig. 5 of the previous paper, blind application of the initial slope criterion would dictate the use of the parabolic line. As mentioned previously this would be a poor choice of line taper.

The criterion which is always valid is more like an average slope criterion which because of the complexity of the transient response of tapered lines can be applied more easily by visual or graphical means than analytically.

Appendix

The quantity n_1 is defined by equation 6 of the companion paper. In Appendix III of that paper it was found that

$$\alpha_1=\rho_{n-1}+\sum_{j=0}^{n-2}\rho_j\rho_{j+1}\text{ and}$$

$$b_1=\rho_{n-1}-\sum_{j=0}^{n-2}\rho_j\rho_{j+1}$$

For that reason the value of n_1 is identical for both the approximate and the exact transient solution to the step line. Hence, by equation 2 of the companion paper

$$n_1=\rho_0\rho_1+\rho_n\rho_{n-1}+\sum_{j=1}^{n-2}\rho_j\rho_{j+1}$$

By division

$$m_1=\rho_0\rho_1+\rho_n\rho_{n-1}+\sum_{j=1}^{n-2}\rho_j\rho_{j+1} \tag{18}$$

If the number of steps used to approximate the tapered line is large enough $\rho_j\cong\rho_{j+1}$. Then equation 18 becomes

$$m_1=\rho_0\rho_1+\rho_n\rho_{n-1}+\sum_{j=1}^{n-2}\rho_j^2$$

where

$$\rho_j=\frac{R_j-R_{j+1}}{R_j+R_{j+1}}\text{ for }0<j<n$$

The coefficient ρ_j may be written

$$\rho(x) = -\frac{R(x+\Delta x)-R(x)}{R(x+\Delta x)+R(x)}$$

where x is a measure of position along the line. Clearly

$$\underset{\Delta x \to 0}{\text{Limit}}\ \rho(x) = \frac{-1}{2}\frac{d}{dx}[\ln R(x)]$$

Since $\Delta x = L/n$, $n \to \infty$ when $\Delta x \to 0$. Under such a condition it can be shown that

$$\sum_{j=1}^{n-2} \rho_j^2 = \frac{1}{4n}\int_0^L \left\{\frac{d}{dx}[\ln R(x)]\right\}^2 dx \qquad (19)$$

Therefore

$$m_1 = \rho_0\rho_1 + \rho_n\rho_{n-1} + \frac{1}{4n}\int_0^L \left\{\frac{d}{dx}[\ln R(x)]\right\}^2 dx \qquad (20)$$

where

$$\rho_0 = \frac{Z_L - R_1}{Z_L + R_1} \text{ and } \rho_n = \frac{R_n - Z_g}{R_n + Z_g}$$

The Transient Response of Tapered Transmission Lines

F. J. YOUNG
ASSOCIATE MEMBER AIEE

E. R. SCHATZ
MEMBER AIEE

J. B. WOODFORD
ASSOCIATE MEMBER AIEE

TAPERED transmission lines are frequently used in communications engineering to transform voltages and impedances. Much has been done in the steady-state analysis[1–12] of these devices. The need remains, however, for a theory of the optimum taper based upon transient considerations because of intrinsic limitations of any steady-state theory. Steady-state treatments are sufficient for a-c applications, but are difficult to apply meaningfully to transient phenomena. Very little has been done in the realm of tapered-transmission line transient analysis. An analysis for exponential tapers has appeared in the literature,[13–16] but there has been no attempt to find the optimum taper from transient considerations.

A criterion for the judgement of various tapered lines can be established on the basis of their performances as pulse transformers. This criterion is easily set up by considering the distortion which a pulse suffers when it is transformed by a tapered line. The main problem of this paper is the determination of the transient response of the tapered line as a function of its terminations and nominal characteristic impedance. A companion paper considers the optimization problem.[17]

In this paper a general expression for the transient response of any tapered transmission line with a constant velocity of propagation to a step-function excitation is derived. To obtain such an expression an aggregation of ordinary transmission lines connected end to end is considered. An exact expression for the response of that circuit is obtained along with an approximate solution which is easier to apply and quite accurate under certain conditions. Both expressions can be written in closed form but their numerical evaluation is long and tedious. For that reason the IBM (International Business Machine Corporation) *650* computer is used and special care is taken to put the analytical solution into a form amenable to digital computation. The transient solution is evaluated for Bessel, hyperbolic, parabolic, and exponential (see Appendix I) lines for two cases: 1. for nominally matched lines at both the input and output, and 2. for lines excited by a generator of zero internal impedance with the load nominally matched.

The Step Line Method of Calculating the Transient Response

For simplicity the tapered transmission lines considered herein are approximated by a large number of cascaded uniform lines of differing characteristic impedances. These lines are joined together in such a manner that the characteristic impedance seen at any position along the assemblage of lines (which will hereafter be called a step line) approximates the nominal characteristic impedance at the corresponding position on the tapered line. Fig. 1 shows how the characteristic impedance of a tapered line can be approximated by the characteristic impedance of a step line. Let the sections of uniform line nearest the sending and receiving ends of the step lines be denoted by n and 1 respectively. The method of finding the transient response of such a step line is outlined in the following; see Fig. 6.

A. 1. Find the impedance Z_{n-1} seen looking into the $(n-1)$th section toward the 1st section.

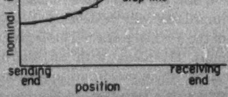

Fig. 1. Characteristic impedance of a step and tapered line versus position along line

Paper 59-15, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted May 14, 1958; made available for printing November 12, 1958.

F. J. Young, E. R. Schatz, and J. B. Woodford are with Carnegie Institute of Technology, Pittsburgh, Pa.

2. Use this impedance Z_{n-1} as a load for the nth section.
3. Apply a signal V_n at the sending end and determine by ordinary transmission line theory the voltage V_{n-1} which appears across the load Z_{n-1} of the nth section.

B. 1. Decrease the subscripts on all voltages and impedances and repeat the operations described previously until the voltage at the receiving end V_0 is found.

Fortunately this method can be applied to a step line of any number of steps or sections and it can be shown that as the number of steps is increased without bound the step line and the tapered line become identical.[18]

In Appendix II a voltage $V_g\ (s,0)$ is supplied to an n-step line by a signal generator whose internal impedance is $Z_g\ (s)$. The step line is terminated in an impedance $Z_L\ (s)$. Using the method outlined in the foregoing the output voltage $V\ (s,L)$ which appears across $Z_L(s)$ is calculated and after much algebraic simplification it becomes

$$V(s, L) = \frac{2V_g(s,0)\epsilon^{\frac{-sL}{c}} \dfrac{R_nR_{n-1}}{R_n+Z_g(s)} \displaystyle\prod_{j=0}^{n-2} \frac{2R_j}{R_j+R_{j+1}}}{\alpha_{n-1}(s)R_{n-1}\left[1+\rho_n(s)e^{-\frac{2sL}{cn}}\right]+ \beta_{n-1}(s)R_n\left[1-\rho_n(s)\epsilon^{\frac{-2sL}{cn}}\right]} \tag{1}$$

where R_j = the surge resistance of the jth section of line for $1 \leq j \leq n$.

$R_0 = Z_L(s)$

$$\rho_n(s) = \frac{R_n - Z_g(s)}{R_n + Z_g(s)}$$

s = the complex frequency
L = total length of the line
n = the number of sections in the line
$R_{n-1}\alpha_{n-1}(s)$ = the numerator of the impedance seen looking into the $n-1$ section of line toward $Z_L(s)$; see equation 20 of Appendix III)
$\beta_{n-1}(s)$ = the denominator of the same impedance
c = the velocity of light

The inverse Laplace transformation of equation 1 yields the exact transient response of the n-step line under consideration. Because equation 1 contains the numerator and the denominator of the impedance seen looking toward the receiving end from the $n-1$th section, a method for the exact determination of this impedance will be developed for the case of the $n-1$ step line. This is given in Appendix III along with an alternate derivation which yields an approximate impedance of a step line.

Equation 1 is the exact transient response of an n-step line. An approximate transient response for such a line can be obtained by substituting equation 23 of Appendix III into equation 1. The result is

$$V(s, L) = \frac{1}{2\xi} V_g(s, 0)\epsilon^{\frac{-sL}{c}} \prod_{j=0}^{n} \frac{2R_j}{R_j+R_{j+1}} \tag{2}$$

where

$$\xi = \left[1+\rho_n\rho_{n-1}\epsilon^{-\frac{2sL}{cn}}\right] \times \left[1+\sum_{i=1}^{n-1}\sum_{j=0}^{n-i-2}\rho_j\rho_{j+i}\epsilon^{-\frac{2Lis}{cn}}\right] + \left[\rho_{n-1}+\rho_n\epsilon^{-\frac{2sL}{nc}}\right]\sum_{j=1}^{n-1}\rho_{n-i-1}\epsilon^{-\frac{2siL}{cn}}$$

If $\rho_n = 0$, equation 2 becomes

$$V(s, L) = \frac{\frac{1}{2} V_g(s, 0)\epsilon^{\frac{-sL}{c}} \displaystyle\prod_{j=0}^{n} \frac{2R_j}{R_j+R_{j+1}}}{1+\displaystyle\sum_{i=1}^{n-1}\sum_{j=0}^{n-i-1}\rho_j\rho_{i+j}\epsilon^{\frac{-2Lis}{cn}}} \tag{3}$$

Equation 3 applies when the signal generator impedance equals the nominal sending-end impedance of the line.

Calculated Transients on Various Lines

It is convenient to calculate the step-function responses of various 100-step lines because such lines approximate tapered lines very well, and the resulting equations lend themselves to quick calculation on an IBM *650* digital computer. Because the responses of these lines are to be compared critically, it is necessary in order to reach sound conclusions that the lines should: 1. be of identical length, 2. possess the same ratio of nominal impedance transformation, 3. be terminated identically, and 4. have applied to them the same input. All lines herein considered have identical nominal input and output surge resistances and are terminated at the output in the nominal output surge resistance. Under the foregoing conditions and provided the internal impedance of the input signal generator equals the input and surge resistance, equation 1 becomes

$$V(s, L) = \frac{V_g(s, 0)\epsilon^{\frac{-sL}{c}} R_{n-1} \displaystyle\prod_{j=1}^{n-2} \frac{2R_j}{R_j+R_{j+1}}}{\alpha_{n-1}(s)R_{n-1}+\beta_{n-1}(s)R_n} \tag{4}$$

The approximate solution given by equation 2 becomes

$$V(s, L) = \frac{\frac{1}{2} V_g(s, 0)\epsilon^{\frac{-sL}{c}} \displaystyle\prod_{j=1}^{n-1} \frac{2R_j}{R_j+R_{j+1}}}{1+\displaystyle\sum_{i=1}^{n-1}\sum_{j=0}^{n-i-1}\rho_j\rho_{i+j}\epsilon^{\frac{-2Lis}{cn}}} \tag{5}$$

Equations 4 and 5 are evaluated for the one to four nominal impedance transforming exponential, Bessel, parabolic, and hyperbolic tapered transmission lines. The mathematical formulas for the surge-resistances of these lines can be found in Appendix I along with a plot of the surge resistances as a function of position on the line. Both equations 4 and 5 assume the form

$$V(s, L) = \frac{K\epsilon^{\frac{-sL}{c}}}{s\left[1+\displaystyle\sum_{j=1}^{99} n_i\epsilon^{\frac{-2Lis}{cn}}\right]} \tag{6}$$

where K = a constant
n_i = numerical coefficients

when numerical values of the various parameters are inserted. The response of the line $V(t,L)$ to a step input can be determined by taking the inverse Laplace transform of $V(s,L)$ given by equation 6. This operation can be simplified by expressing $V(s,L)$ in the form

$$V(s, L) = \frac{K}{s}\left[1-\sum_{j=1}^{\infty} m_i\epsilon^{\frac{-2siL}{cn}}\right]\epsilon^{\frac{-sL}{c}} \tag{7}$$

where m_i = numerical coefficient

The inverse Laplace transform of equation is given by

$$V(t, L) = K\left\{u\left[t-\frac{L}{c}\right] - \sum_{j=1}^{\infty} m_i u\left[t-\frac{2Li}{cn}-\frac{L}{c}\right]\right\} \tag{8}$$

where $u(t-\tau)$ = the unit step function

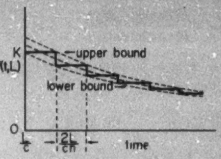

Fig. 2. Typical plot of V(t, L) versus t

For example, a typical plot of $V(t,L)$ versus t is illustrated in Fig. 2. The function in Fig. 2 that looks like a stair case is the transient on a step line. The curves which are dotted in are what would be expected as a result if the number of steps were infinite. Choice of a curve such as any of the dotted curves should insure a good approximation to the transient on a tapered line. Because the upper and lower curves can be thought of as upper and lower bounds on the transient solution of a tapered line, the curves plotted hereafter will not be stair case functions but will be instead smooth curves which are the means between the upper and lower bounds. Such a mean curve is shown in Fig. 2. This method of finding the transient response of a tapered line from the step line response yields the correct value of output at the time, $t=L/c$.

Response of lines which are matched nominally at the load and are fed by a signal generator whose internal impedance equals the complex conjugate of the nominal input impedance. The transient responses of these nominally matched lines are shown in Figs. 3(A) and 3(B). For the lines investigated the approximate results of equation 5 shown in Fig. 3(B) agree closely with the more exact results of equation 4 which are shown in Fig. 3(A). The two solutions are almost identical during the interval $1<tc/L<1.3$, but as tc/L increases the difference between solutions grows slightly larger and the approximate results appear to approach a slightly wrong final value as $tc/L\rightarrow\infty$. The more exact results, however, have a final value which is correct to eight significant figures. It can be seen from both Figs. 3(A) and (B) that the output of the exponential line decays more slowly during the interval $1<tc/L<1.65$ than the output of the other lines investigated. Of the lines investigated the hyperbolic line has the most rapidly fading transient. It also appears that the more negative the slope of the quantity $V(L/c,L)/V_0$ the quicker the transient dies away. However, no general conclusions can be drawn on the basis of only four different tapered lines and it is to be emphasized that everything stated thus far is known to be true only for the four cases investigated.

Response of lines which are nominally matched at the load and are fed by a signal generator of zero internal impedance. In the case of the lines just discussed the signal generator at the sending end consisted of a battery of voltage V_0, in series with a switch which is in series with an impedance having a value equal to the complex conjugate of the nominal impedance of the tapered line at the sending end. In this section the impedance which is in series with the ideal battery and switch is replaced by a short circuit. Fig. 4 shows the exact response on the lines considered. Under these terminations the behavior of the lines is quite different than it was in the previous section. In this case the hyperbolic line transient dies off least rapidly in the interval $1<tc/L<1.5$ and the exponential line is next best in that respect in the interval. In the smaller interval $1<tc/L<1.2$ the parabolic line transient decays more slowly than the exponential or Bessel line transients. Throughout the time intervals discussed the Bessel line's output is less than the output of the other lines. However, the Bessel line transient approaches its steady state with small oscillations whereas the hyperbolic line transient shows a marked degree of oscillation.

Conclusions

It can be seen that in the cases considered the exact and the approximate method of calculating transients on step lines yields very similar answers. This is particularly true for small values of tc/L where the results are almost identical. Thus, if it is desired to calculate only the initial part of a transient on a line the approximate method can be used to save time and effort.

Comparison of Figs. 3(A) and 4 indicates that the value of the internal impedance of the signal generator plays a very great role in the transient response of any given line. In most steady-state theories the line terminations have not been taken into account.

From the results obtained it appears that, with a given criterion in mind, for a fixed length of line and a fixed ratio of nominal impedance transformation there exists an infinity of optimum lines. More precisely, one optimum line might exist for each possible set of terminations. The companion paper established a criterion for the judgment of tapered lines, applied the criterion to a special case to find an optimum line, and considered the case of general terminations at both the input and the output.

Nomenclature of Tapered Transmission Lines

A transmission line having a characteristic impedance which varies with position along its length is called a tapered transmission line or a transmission-line-type pulse transformer. In the literature there are three or more distinct methods for naming such lines which often cause much confusion.[11] Many authors name their lines after the distributed inductance function. Examples of this are the exponential, hyperbolic, and parabolic lines. Some lines are known by the mathematical form of their logarithmic derivative of inductance function, e.g., the Gaussian line. A few lines are named after their own differential equation of voltage providing it is a well-known equation with a simple name. The Bessel line is named in that manner but is sometimes referred to as the linear line. In order to avoid any ambiguities which might arise from nomenclature, the tapered lines treated herein are tabulated in Table I along with their nominal characteristic impedance functions and their step-line approximations. (The nominal characteristic impedance Z_0 at a point on a line is the value of $\sqrt{l'/c'}$ one would calculate at that point from the physical dimensions of the line. A nominally matched line is terminated by a resistance which equals the nominal characteristic impedance of the line at the termination.)

Table I. Exact and Approximate Mathematical Forms of the Surge Resistances of the Lines Considered

Name of Line	Mathematical Form of R(x)	Step-Line Form of R(x)
Exponential	$\frac{R(x)}{R(0)}=\exp\left[\frac{x}{L}\ln\frac{R(L)}{R(0)}\right]$	$\frac{R_i}{R(0)}=\exp[1.40029(1-0.01i)]$ where $i=1, 2, 3\ldots 100$
Parabolic	$\frac{R(x)}{R(0)}=1+3\left[\frac{R(L)}{R(0)}-1\right]\frac{x^2}{L^2}-2\left[\frac{R(L)}{R(0)}-1\right]\frac{x^3}{L^3}$	$\frac{R_i}{R(0)}=1+9.0026828(1-0.01i)^2-6.0017885(1-0.01i)^3$
Hyperbolic	$\frac{R(x)}{R(0)}=\frac{1+\frac{R(L)}{R(0)}}{2}+\frac{1-\frac{R(L)}{R(0)}}{2}\tanh 6\left[\frac{x}{L}-\frac{1}{2}\right]$	$\frac{R_i}{R(0)}=2.5-1.5\tanh 6[1.0101010(1-0.01i)-0.5]$
Bessel	$\frac{R(x)}{R(0)}=1+\left[\frac{R(L)}{R(0)}-1\right]\frac{x}{L}$	$\frac{R_i}{R(0)}=1+3.0303030(1-0.01i)$

The Lines Used in This Paper

Let $x=0$ at the sending end and $x=L$ at the receiving end of the lines. Table I gives the name of the line, the general form of its characteristic impedance, and the exact numerical form of its characteristic impedance as used in this paper. Because only lossless lines are considered the characteristic impedance is sometimes called the surge resistance $R(x)$. Fig. 5 is a plot of the surge resistance of the step lines tabulated on Table I.

Appendix II

The Detailed Derivation of the Output Voltage of an N-Step Line

Consider the step line shown in Fig. 6. This line is composed of n sections of uniform equal length transmission line. The number i to the left of each section of line is the number of that section. The surge resistance of the ith section of line is R_i and Z_i is the impedance seen looking into the ith section. From ordinary transmission line theory

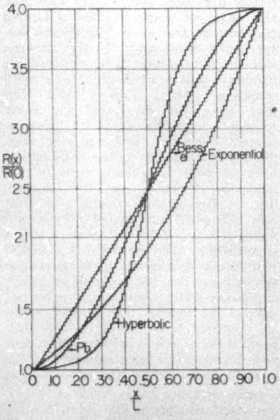

Fig. 5. Plot of the surge resistance versus position for the 1 to 4 impedance transforming Bessel, exponential, parabolic, and hyperbolic step lines

$$V_n=\frac{V_{n-1}}{2}\left\{\left[1+\frac{R_n}{Z_{n-1}}\right]\epsilon^{\theta}+\left[1-\frac{R_n}{Z_{n-1}}\right]\epsilon^{-\theta}\right\} \tag{9}$$

$$I_n=\frac{V_{n-1}}{2}\left\{\left[\frac{1}{Z_{n-1}}+\frac{1}{R_n}\right]\epsilon^{\theta}+\left[\frac{1}{Z_{n-1}}-\frac{1}{R_n}\right]\epsilon^{-\theta}\right\} \tag{10}$$

where

$\theta=s\Delta L/c$
$s=$complex frequency
$c=$the velocity of light
$\Delta L=$length of each section of line
$V_s=$the sending end voltage
$I_s=$the sending end current
$V_{n-1}=$the voltage impressed upon the $n-1$ section of line

Application of Kirchhoff's voltage law at the sending end yields

$$V_n+I_nZ_g=V_g \tag{11}$$

Upon substitution of V_n and I_n as given by equations 9 and 10 respectively equation 11 becomes

$$\frac{2V_n\epsilon^{-\theta}}{\left[1+\frac{Z_g}{R_n}+\frac{R_n+Z_g}{Z_{n-1}}\right]+\left[1-\frac{Z_g}{R_n}-\frac{R_n-Z_g}{Z_{n-1}}\right]\epsilon^{-2\theta}}=V_{n-1} \tag{12}$$

Repeated application of the recursion relationship stated in equation 12 yields

$$\frac{[2\epsilon^{-\theta}]^nV_g}{\left\{\left[1+\frac{Z_g}{R_n}+\frac{R_n+Z_g}{Z_{n-1}}\right]+\left[1-\frac{Z_g}{R_n}-\frac{R_n-Z_g}{Z_{n-1}}\right]\epsilon^{-2\theta}\right\}\times\prod_{i=1}^{n}\left\{1+\frac{R_i}{Z_{i-1}}+\left[1-\frac{R_i}{Z_{i-1}}\right]\epsilon^{-2\theta}\right\}}=V_0 \tag{13}$$

The product in the denominator of equation 13 causes that expression to be exceedingly unwieldy for $n>2$. However, if any two adjacent factors of the product are multiplied together great simplification follows. The product of all the factors so obtained is

$$\prod_{i=1}^{n-1}\left\{1+\frac{R_i}{Z_{i-1}}+\left[1-\frac{R_i}{Z_{i-1}}\right]\epsilon^{-2\theta}\right\}=\alpha_{n-1}\prod_{j=0}^{n-2}\frac{R_j+R_{j+1}}{R_j} \tag{14}$$

where α is defined in Appendix III. Substitution of equation 14 into equation 13 yields

$$V_0=\frac{2V_g\epsilon^{-n\theta}\frac{R_nR_{n-1}}{R_n+Z_g}\prod_{j=0}^{n-2}\frac{2R_j}{R_j+R_{j+1}}}{\alpha_{n-1}R_{n-1}[1+\rho_n\epsilon^{-2\theta}]+\beta_{n-1}R_n[1-\rho_n\epsilon^{-2\theta}]} \tag{15}$$

where

$$\rho_n\equiv\frac{R_n-Z_g}{R_n+Z_g},\ R_0\equiv Z_L,\ \alpha_0\equiv 1 \text{ (see Fig. 6)}$$

and β is defined in Appendix III.

Appendix III

By ordinary transmission-line theory the impedance seen looking into a length of uniform transmission line is

$$Z_{in}=\frac{1+\frac{Z_L-Z_0}{Z_L+Z_0}\chi}{1-\frac{Z_L-Z_0}{Z_L+Z_0}\chi}Z_0 \tag{16}$$

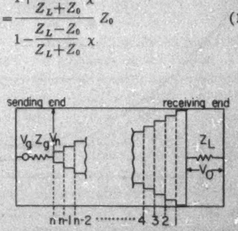

Fig. 6. Sketch of a typical step line which illustrates the method of denoting various sections of line

Vol
Pt.
195

where

ΔL = the length of the section of line
c = the velocity of light
s = complex frequency
Z_0 = the characteristic impedance of the section of line
Z_L = the load impedance
$\chi = \epsilon^{\frac{-2s\Delta L}{c}}$

The step line whose input impedance is being sought is composed of $n-1$ ordinary transmission lines connected end to end. Let the characteristic impedance of the ith line be denoted by R_i. Then for example, the characteristic impedance of the first line which is the one nearest the load and the $n-1$ the line are given by R_1 and R_{n-1} respectively. By application of equation 16 the impedance Z_1 seen looking into the first section of line is

$$Z_1 = \frac{1+\rho_0\chi}{1-\rho_0\chi} R_1 \qquad (17)$$

where

$$\rho_0 \equiv \frac{Z_L - R_1}{Z_L + R_1}$$

For convenience let

$$\rho_i \equiv \frac{R_i - R_{i+1}}{R_i + R_{i+1}}$$

The impedance Z_1 is the load of section 2. The impedance Z_2 seen looking into section 2 calculated by the use of equation 16 is

$$Z_2 = \frac{1+(\rho_1+\rho_0\rho_1)\chi + \rho_0\chi^2}{1-(\rho_1-\rho_0\rho_1)\chi - \rho_0\chi^2} R_2 \qquad (18)$$

Similarly

$$Z_3 = \frac{1+(\rho_2+\rho_0\rho_1+\rho_1\rho_2)\chi + (\rho_1+\rho_0\rho_2+\rho_0\rho_1\rho_2)\chi^2 + \rho_0\chi^3}{1-(\rho_2-\rho_0\rho_1-\rho_1\rho_2)\chi - (\rho_1-\rho_0\rho_2-\rho_0\rho_1\rho_2)\chi^2 - \rho_0\chi^3} R_3 \qquad (19)$$

For values of $n>3$, Z_n becomes extremely cumbersome. It would be most convenient if Z_n could be obtained without first calculating $Z_1, Z_2, \ldots Z_{n-1}, Z_n$. The knowledge of Z_{n-1} in literal form would enable the transient response of any step line to be exhibited in a form which would be quite useful for the purpose of generalization. An approximate literal value of Z_n has been determined by the process of ordinary induction. Inspection of equations 17, 18, 19, and many similar equations for impedance which are too lengthy to include here, indicates that the impedance Z_n will be of the form

$$Z_n = \frac{1+\sum_{i=1}^{n} \alpha_i\chi^i}{1-\sum_{i=1}^{n} a_i\chi^i} R_n \qquad (20)$$

The coefficient a_i and b_i appear to be of the form

$$a_i = \rho_{n-i} + \sum_{j=0}^{n-i-1} \rho_j\rho_{i+j} + \gamma_i \qquad (21)$$

$$b_i = \rho_{n-i} - \sum_{j=0}^{n-i-1} \rho_j\rho_{i+j} - \delta_i \qquad (22)$$

where γ_i and δ_i are third or higher order products of various combinations of the reflection coefficients $\rho_i(1 \leq i \leq n)$. In all cases worked out in this investigation, $\gamma_1 = \delta_1 = 0$. The other values of the coefficients γ_i and δ_i do not lend themselves to this inductive process. Because $\rho_i < 1$ the possibility exists that

$$|\gamma_i| \ll \left| \rho_{n-i} + \sum_{j=0}^{n-i-1} \rho_j\rho_{i+j} \right|$$

and

$$|\delta_i| \ll \left| \rho_{n-i} - \sum_{j=0}^{n-i-1} \rho_j\rho_{i+j} \right|$$

If the foregoing conditions are fulfilled the impedance Z_n is given by

$$Z_n = \frac{1+\sum_{i=1}^{n}\left[\rho_{n-i} + \sum_{j=0}^{n-i-1} \rho_j\rho_{j+i}\right]\chi^i}{1-\sum_{j=1}^{n}\left[\rho_{n-i} - \sum_{j=0}^{n-i-1} \rho_j\rho_{j+1}\right]\chi^i} R_n \qquad (23)$$

Equation 23 yields an approximate value of impedance for the step line. The exact value of impedance for a line of about 100 steps is indeed lengthy if written out in literal form. It is of the form

$$Z_n = \frac{\alpha_n}{\beta_n} R_n \qquad (24)$$

However, for any given tapered line it is a straightforward task to program an IBM *650* computer to calculate α_n and β_n by successive application of equation 16. The computer can also be programmed to find them by using equation 23. The IBM *650* was used in this manner to calculate the transients by both the exact and inexact method. The exact method used 2 hours of computing time and the approximate method used only one hour to find the complete transient solution to one line.

Nomenclature

a_i = coefficients of the power series in the numerator of Z_n
b_i = coefficients of the power series in the denominator of Z_n
c = velocity of light in the dielectric
c' = capacitance per unit length of line
ϵ = Euler's number
I_n = Laplace transformed current at the sending end of the step line
i = subscript of quantities pertaining to the ith section of uniform line
j = subscript of quantities pertaining to the jth section of uniform line
K = magnitude of the numerator of equation 5
l' = inductance per unit length of line
L = total length of the tapered line
n = number of steps used
n_i = numerical coefficients of the power series contained in equation 6
m_i = numerical coefficients of the power series contained in equation 7
O = subscript pertaining to the load end or receiving end of the tapered line
R_j = surge resistance of the jth section of uniform line
R_{n+1} = internal impedance of the signal generator
R_O = load impedance
s = complex frequency
t = time
$u(t-\tau)$ = unit step function ,which appears at $t=\tau$
V_i = Laplace transformed voltage at the ith section of uniform line
V_n = Laplace transformed voltage at the input or sending end of the tapered line
$V_O = V(s, L)$ = Laplace transformed voltage at the output or receiving end of the tapered line
$V_g(s, 0)$ = Laplace transformed voltage of the signal generator
$V(t, L)$ = output voltage of the line as a function of time
x = position along the tapered line measured from the sending end
Z_i = impedance seen looking toward the load into the ith section of uniform line
Z_g = internal impedance of the signal generator
Z_L = load impedance
$\alpha_0 = 1$
α_n = the numerator of equation 24
β_n = denominator of equation 24
γ_i = third and higher order products of reflection coefficients in numerator of Z_n
δ_i = third and higher order products of reflection coefficients in denominator of Z_n
ΔL = length of each section of uniform line ($\Delta L = L/n$)
$\theta = s\Delta L/c$
2ξ = denominator of equation 2
Π = standard symbol denoting products
ρ_i = nominal reflection coefficient at the ith section of uniform line
Σ = standard symbol denoting summation
τ = time delay
$\chi = \epsilon^{-2\theta}$

Discussion

L. O. Barthold (General Electric Company, Schenectady, N. Y.): The authors have done a very thorough job in their analysis of the complex problem of nonuniform transmission lines. An approximate solution of the same problem was recently reported in the literature.[1] The latter solution was made in conjunction with investigations of the response of transmission towers to lightning strokes.

In the approximate solution referred to, the line is considered first as a stepped line, but as opposed to the authors' assumption, the steps are taken in equal impedance ratios instead of equal electrical distances. This results in the same reflection and refraction coefficients at each junction.

The solution was made from a generalized lattice diagram in which the number of steps was made to approach infinity. The important approximation made was in neglecting all waves which appear with reflection coefficients of second and higher orders.

For the case where the nominal surge resistance of the line is matched at both ends, the above assumption leads to the general expression

$$\frac{V(t,0)}{V_s}=1+\frac{1}{2}\log_e\frac{R\left(\dfrac{tc}{2L}\right)}{R(0)}$$

Since the reflected terms at the sending end appear with only odd powers of the reflection coefficient, the terms which are omitted here are third order and higher and the approximation is a reasonably good one.

Given the nominal surge resistance as a function of travel time, the foregoing solution can be made very quickly by hand calculation.

The same analysis applied to receiving end voltage omits second and higher order terms which, as the authors show, are quite significant. The foregoing approximation is correct in this case only for the initial value of the receiving-end voltage.

Since the assumption of equal impedance ratio steps greatly simplifies the generalized lattice approach, do the authors feel that this assumption might simplify the solution they have made?

Also, since the ultimate solution made by the authors is the summation of a finite series of uniform line segments, it would seem that an equally good approximation could be obtained by representing the line as a lumped parameter circuit. It would be interesting to know if the authors considered this approach.

REFERENCE

1. AN APPROXIMATE TRANSIENT SOLUTION OF THE TAPERED TRANSMISSION LINE, **L. O. Barthold.** *AIEE Transactions*, vol. 77, pt. III, 1957 (Feb. 1958 section), pp. 1556–61.

F. J. Young, E. R. Schatz, J. B. Woodford: The authors are grateful for Mr. Barthold's comments. It is gratifying to know that his theory based on equal steps of impedance checks with the initial values of the output voltage calculated by our equations. The authors briefly considered using such an approach but because it did not permit mathematical generalization as easily as the equal length method it was abandoned. Thus, in the authors' opinion the equal impedance steps would not have simplified the solution.

Representation of a transmission line by lumped parameters is not a good approximation at all frequencies. Since transients are being investigated and therefore high-frequency components, an exorbitantly large number of lumped elements might be necessary to obtain an adequate approximation, perhaps more than the number of transmission-line elements finally chosen for this work.

A Single-Stator Meter for Two Phases of a 4-Wire Y

E. W. SCHWARZ
MEMBER AIEE

Synopsis: By modification of a 3-wire single-phase meter, a single-stator watt-hour meter has been developed for the measurement of two phases of a 4-wire Y 3-phase distribution system. The paper discusses the modifications of the meter together with its performance characteristics.

WHEREVER a 4-wire Y 3-phase distribution system is in use and from which energy is derived by means of two phases and the neutral, there arises the problem of metering the 3-wire system, so-called "network service." The usual method of metering the 3-wire network system is by means of a 2-stator polyphase meter, which essentially consists of two electromagnetic structures, each of which has a voltage and current coil. While present-day production and design techniques have reduced the cost of the 2-stator network meter, there still remains a considerable price differential between the network meter and a 3-wire singlephase meter. It has been the desire of utilities and meter manufacturers to provide a watt-hour meter that would be applicable for network metering, yet substantially less in cost than that of a 2-stator polyphase meter.

A single-stator meter has been developed and is being manufactured that will measure the energy of a network system. Its cost is considerably less than that of a 2-stator network meter.

While there is a definite price advantage in the use of single-stator network meters, utilities interested in their possibilities should not overlook certain disadvantages. They will have to make the final decision as to the importance of cost savings versus usage and testing disadvantages.

The Current Electromagnet Structure

As previously stated, the design of the single-stator meter (Fig. 1) was developed with the primary purpose of

Y., February 1–6, 1959. Manuscript submitted October 14, 1958; made available for printing November 13, 1958.

E. W. SCHWARZ is with the Sangamo Electric Company, Springfield, Ill.

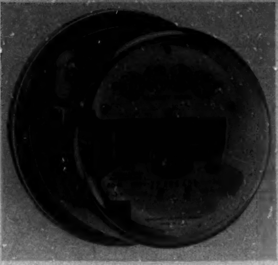

Fig. 1. Single-stator network meter

effecting the maximum possible cost reduction from that of the 2-stator network meter. Consequently, the decision was made to use the single-stator 3-wire single-phase meter as the building block for the single-stator network meter. There are two possible choices in converting the single-stator construction into a network meter. One choice consists of using phase-to-phase voltage for the voltage coil, which dictates changing the phase of both line currents inside the meter. While this scheme was considered, it was felt that the addition of two resistors and two reactors necessary to accomplish the aforementioned phase shifting was not advisable in order to achieve the maximum possible cost reduction.

The other possible solution, and the one that has achieved the major objective, is the use of phase-to-neutral voltage for the voltage coil, resulting in the requirement that only one line current need be shifted in phase. For this scheme only one resistor and one leakage core are required to convert the single-stator 3-wire single-phase construction for use on network service.

The current electromagnetic structure is illustrated in Fig. 2. There are two current coils wound on a common laminated core. The upper coil is a 2-turn coil connected in line A as shown in Appendix I. The lower coil is an 8-turn coil connected in line B. As illustrated in Appendix I, the current I_C through the 8-turn coil must lag the line current I_B by 60 degrees, which implies, since I_B lags the voltage E, that the current I_C must lag the voltage E by some angle greater than 60 degrees. To accomplish the necessary phase shift of I_C, an 8-turn coil was chosen, which increases the ratio of the inductive reactance to resistance of the coil. In addition, a laminated leakage core, so designed as to be movable with respect to the main laminated core, is located between the 2- and 8-turn coils. Not only must the phase of I_C be precisely adjusted, but the magnitude of I_C must be such so that for comparable line currents the torque-producing flux from the 8-turn coil has the same magnitude as the torque-producing flux from the 2-turn coil. Stated another way, the magnitude of I_C must also be adjustable in addition to its phase. In order to complete the adjustment of magnitude and phase of I_C, a manganin resistor is riveted and brazed across the 8-turn coil. The resistance of this shunt is adjusted by removing material. To summarize the foregoing statements, it is possible to obtain correct phase and magnitude of the current in the 8-turn coil by adjusting the position of the leakage core and changing the resistance of the resistor. These two adjustments are preset in the manufacturing process and need not be altered.

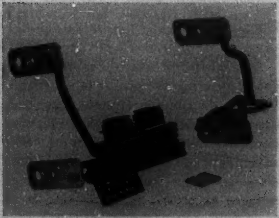

Fig. 2. Current electromagnetic assembly

Pole-tip extensions are placed between the poles of the current core structure in order to obtain additional torque. In this manner the effective pole area of the current core is increased, resulting in increased driving torque.

All current carrying parts of the current electromagnetic structure have been designed to carry 60 amperes continuously while still maintaining a tolerable temperature rise inside the meter. The meter is therefore rated as a class *60* meter. Since the thermal characteristics limit the maximum current to 60 amperes, and as a result of using the same slow disk speed of a single-phase meter with a $K_h=6$, it was determined that no overload compensation was necessary, a factor again favorable in reducing the cost.

The Voltage Electromagnetic Structure

In Fig. 3 the various components of the voltage electromagnetic assembly are shown. The number of turns and wire size of the voltage coil were changed from that of a standard 120-volt single-phase coil in order to obtain additional driving torque. Even so, the watts loss in the potential coil is not excessive and, in fact, is 25% less than the watts loss of a comparable 2-stator meter. The power-factor adjustment consists of a phasing band, the resistance of which is altered in order to adjust the meter for lagging power-factor loads. This adjustment is also preset in manufacture and eliminates the need for any counter compensation of the current electromagnetic core. Class II temperature compensation is accomplished by the addition of temperature-sensitive nickel-steel to the phasing-band assembly. The light-load adjustment is the same as that used for certain single-phase meters, and consists of a movable vane, the position of which compensates any light-load inaccuracies.

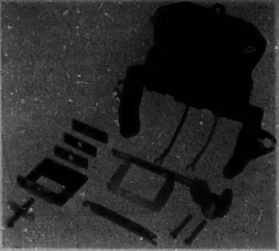

Fig. 3. Voltage electromagnetic assembly

Only the light-load and full-load adjustments are available for future recalibration. The coil-balance and power-factor adjustments having been fixed during manufacture.

The Phase-Sequence Indicator

In Appendix I, the necessity of correct phase sequence for proper operation of single-stator network meters becomes apparent. To insure that at the time of installation the phase sequence is correct, a phase-sequence indicator is supplied as an integral part of the meter. The indicator consists of two resistors, a capacitor, and a neon bulb, all encapsulated in an epoxy resin. When incorrect phase sequence is applied to the meter, the neon bulb will light. When correct phase sequence is applied, the bulb will not light. In this manner, correct installation is assured, and if at any time the phase sequence is reversed, an alarm is readily available.

Testing Procedures

The calibration and testing of single-stator network meters is not as straightforward as a single-phase meter. The basic difficulty is that of assuring balanced voltages in the testing procedures. Because of the fact that there are many possible ways of testing, some of which may be more applicable to certain utilities than others, this discussion will only describe one possible procedure.

Appendix II illustrates a test circuit applicable for use in testing the single-stator meter for line-to-line loading. If the distribution system is well balanced (magnitude and phase), it is not necessary to resort to phase-shifting networks. If there is some doubt as to the degree of balance of the voltages, it is not too difficult to construct very accurate phase-shifting networks that eliminate the need for maintaining voltage balance. Such networks operate from the 120 volts that would be applied to the potential coil of the meter under test, and produce a voltage having a magnitude of 208 volts which leads the 120 volts by 30 degrees. In this manner the rotating standard operates at unity power factor when a unity power-factor load is applied to the meter. A 50% lagging power-factor test can be made by the usual practice of cross-phasing the current.

Table I. Characteristic Data of Single-Stator Network Meter

Rated watts	3,600
K_h, watt-hours/revolution	6.0
Maximum current, amperes	60
Torque at rated watts, millimeter-gram	40.0
Potential Circuit Data at 120 volts:	
Loss, watts	1.5
Potential exciting current, amperes	0.093
Current Circuit Data at 15 amperes:	
Loss, watts	0.28
Volt amperes	0.29

For the balancing adjustments between the two coils, the registration of the 2-turn coil is compared with that of the 8-turn coil at both unity and 50% lagging power factor. The registration of the 2-turn coil is easily obtained by a standard single-phase test. A scheme similar to that shown in Appendix II can be used for obtaining the registration of the 8-turn coil. In this case the phase-shifting network must be designed to produce a voltage that is shifted 60 degrees from the input voltage. By the use of such phase-shifting networks there is no need for maintaining a balanced 3-phase supply at any time in the calibration procedure. The foregoing procedure guarantees correct calibration for line-to-neutral and line-to-line loading.

The simplest field test that could be used would consist of testing the 2-turn coil. This coil, since it does not shift the phase angle of the line current, can be tested by a standard single-phase test and will indicate possible deviations in the other calibrations due to the common-core structure used in the single-stator construction.

As mentioned previously, it is usually advisable because of possible differences between utility practices and state codes to discuss the type of test more appropriate for the user.

Meter Accuracy

While discussions of construction and design details of watt-hour meters may be of academic and practical interest to utilities, the ultimate criteria for acceptance is, of course, the degree of accuracy with which a particular design will indicate the true energy delivered to a load.

Fig. 4 indicates the average load curve accuracy of the meter. Since both line-to-line and line-to-neutral loading is important, separate curves are shown for both cases. Voltage variation and temperature variation accuracies are shown in Fig. 5. While it is seen that the accuracy curves are not quite as favorable as those for a 2-stator polyphase meter, it is felt that they are of sufficient accuracy for present-day metering practices.

In Table I are listed miscellaneous data for the single-stator meter.

Conclusions

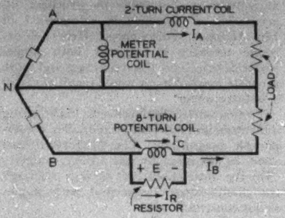
A single-stator watt-hour meter for use in metering two phases of a 4-wire Y 3-phase distribution system has been described wherein the primary objective has been that of cost reduction. The advantages and disadvantages have been discussed along with the major design changes necessary in converting a 3-wire single-phase meter into a single-stator network meter. The accuracies,

Vol.
Pt. 1
1959

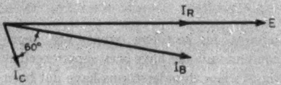
while not identical with those of a multi-stator meter, are well within commonly accepted standards.

Appendix I

Discussion of 60-Degree Phase Shift



E_{BN} lags E_{AN} by 120 degrees



It is possible to demonstrate why the current I_C must lag the line current I_B by 60 degrees by considering the following expressions.

If $E_{AN}(I_A)$ is defined as the dot product of the two vectors E_{AN} and I_A, the power P to the load then becomes

$$P=E_{AN}(I_A)+E_{BN}(I_B)$$

For balanced voltages and ABC phase sequence

$$E_{BN}=E_{AN}\epsilon^{-j120}$$

therefore

$$P=E_{AN}(I_A)+E_{AN}\epsilon^{-j120}(I_B)$$

Now if I_C is chosen such that

$$I_B=KI_C\epsilon^{j60}$$

where K is a positive real constant

$$P=E_{AN}(I_A)+E_{AN}\epsilon^{-j120}(KI_C\epsilon^{j60})$$

which can be expressed as

$$P=E_{AN}(I_A)+E_{AN}\epsilon^{-j120}(KI_C\epsilon^{-j120}\epsilon^{j180})$$

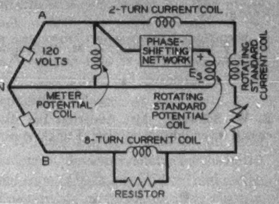
or

$$P=E_{AN}(I_A)+E_{AN}(-KI_C) \text{ qed}$$

The constant K is accounted for in the design of the meter by the proper choice of the number of turns of the current coil and value of the shunting resistor. The minus sign merely indicates that the winding direction of the coil must be reversed from that direction which would normally be used.

Appendix II

One Possible Test Procedure for Checking Type JNS Meter for Line-to-Line Loading



The phase shifting network is designed such that the magnitude of E_S equals 208 volts and such that the phase of E_S leads E_{AN} by 30 degrees.

◆

Discussion

J. Anderson (General Electric Company, Somersworth, N. H.): This paper is an excellent addition to the literature on watt-hour meters. The discusser would like to comment on the author's pertinent advice to utilities that they weigh certain disadvantages of single-stator network meters and then decide for themselves the importance of cost savings versus usage and testing disadvantages. It should be emphasized that the significance of these disadvantages is dependent on the size of the utility, the quantity of network meters being used, and the characteristics of the power distribution system. Thus these factors are not of any major significance for large urban utilities using large quantities of network meters and having a distribution system with a high degree of voltage and frequency stability.

The major use disadvantage is the necessity of obtaining the correct phase sequence and applies to any single-stator network meter. Color-coded wiring, together with the proper wiring specifications, is being effectively used by utilities to overcome this difficulty.

A second major disadvantage is the difficulty of testing. The meter described in this paper cannot be tested with standard single-phase meter test equipment and procedure. This is because this meter cannot be tested with the current coils connected in series and with a voltage applied which is in phase with the load current. Appendix II points out one possible test procedure for line-to-line loading which is equivalent to a normal single phase meter test procedure. However, this procedure requires special test equipment having a phase shifting network to supply potential excitation of the proper magnitude and phase angle to the potential coil of the watt hour standard.

The alternate design with 2-phase shifting networks, mentioned by Mr. Schwarz at the outset of his paper, does not have this testing disadvantage. It can be shop or field tested by utilities with exactly the same equipment and procedure as they are presently using for single-phase 3-wire meters. This can be readily understood by recognizing that when this meter measures a line-to-line load on a normal network service the voltage applied to the potential coil of the meter is the voltage applied to the load. The normal 3-wire single-phase meter test applies voltage and current which are in phase. Utilities using very large numbers of network meters may be able to justify special test equipment; however, the ability to test a single-stator network meter with existing equipment would appear to be highly desirable for those utilities using only a moderate number of these meters. It is of course necessary in the manufacture and factory calibration of either type of network meter to have accurately balanced voltages with precise control of both magnitude and phase angle, which is very practical for a manufacturer to achieve with special test equipment.

A further design and application consideration for single-stator network meters involves evaluating the effect of voltage unbalance. The alternative design of network meter utilizes the line-to-line voltage which is the vector sum of the two line-to-neutral voltages. This meter was described in a paper by McQuarrie.[1] The voltage error seen by this meter is comparable with that of the standard 3-wire single phase meter which also utilizes the sum of the line-to-neutral voltages. The meter design described by Mr. Schwarz utilizes only one of the two line-to-neutral voltages and therefore is subject to relatively larger errors with voltage unbalance at higher power factors as compared with the alternative single-stator network meter.

A tabulation of comparative voltage errors is given in Table II.

Two final considerations that utilities should weigh are performance with varying frequency and power factor. Single-stator network meters in general are more frequency sensitive than the conventional 2-stator network meters. While the meter described in this paper is considerably more frequency sensitive than the alternative design for line-to-line loading (208-volt

Table II. Comparative Voltage Errors

Power Factor	Meter Described in Paper; Calculated Voltage Error, %	Alternative Design; Calculated Voltage Error, %
1.0% voltage unbalance		
Balanced line-neutral load		
1.0	±0.50	±0.01
0.8	±0.50	±0.22
0.5	±0.50	±0.50
Line-line load		
1.0	±0.50	0
0.8	±0.28	0
0.5	±0.01	0
2.5% voltage unbalance		
Balanced line-neutral load		
1.0	±1.25	±0.02
0.8	±1.25	±0.50
0.5	±1.25	±1.25
Line-line load		
1.0	±1.25	0
0.8	±0.75	0
0.5	0	0

loads), these errors probably are not significant when used on the closely controlled frequency of almost all of today's modern power systems.

In general, the low power factor performance of single-stator network meters is significantly poorer than that of 2-stator meters. However, it does meet the requirements of the Code for Electricity Meters, and it is probable that the accuracy obtained, when these meters are used on the normal network loads having reasonably good power factors, will be considered satisfactory.

REFERENCE

1. Watt-Hour Meter for Two Phases of a 4-Wire Y 3-Phase System, A. M. McQuarrie. *AIEE Transactions*, vol. 77, pt. I, May 1958, pp. 152–56.

E. W. Schwarz: Mr. Anderson has discussed several disadvantages of single-stator network meters, two of which will be commented upon in this closure.

One of the difficulties mentioned is that of testing. The alternative design mentioned by Mr. Anderson also requires special test equipment whenever a check is desired for balance between the two current circuits. This is because both line currents are shifted in phase internally by the use of two phase-shifting networks. The design described in the paper also requires special equipment or balanced voltages when testing the meter with its current circuits in series. It should be realized that one of the current circuits can be checked (and also used) as a 2-wire single-phase meter. Consequently, it seems as if both designs have their own testing difficulties.

Regarding the comments pertaining to errors introduced by voltage unbalance, the particular types of voltage unbalance and associated errors as described do exist in single-stator meters. The author might mention that there exist other types of voltage unbalance, particularly on unbalanced loads, wherein the alternative design would have comparable errors and wherein the described design would have no error.

Once again, without resorting to figures, both designs are subject to errors introduced by voltage unbalance. Even so, the probable errors that might be encountered by such unbalances have the same order of magnitude as the inherent overload inaccuracies as described in reference 1 of Mr. Anderson's discussion. Hence, if extreme accuracy is required, both single-stator designs have disadvantages and more accurate measurement would result by using a 2-stator meter.

To summarize, both schemes have testing difficulties and inherent inaccuracies of comparable magnitude. The final conclusion must be obtained by the utility, namely, "Do the anticipated cost savings outweigh the disadvantages associated with single-stator construction?"

Electrical Protection for Transistorized Equipment

D. W. BODLE
MEMBER AIEE

J. B. HAYS, JR.
MEMBER AIEE

THE TREND TO miniaturization of components and the expanding use of transistor circuitry in communication equipment has necessitated the development of new protection measures capable of limiting foreign potentials and currents to values much lower than has heretofore been necessary.

Older conventional equipment was designed to co-ordinate with protector discharge gaps having a minimum nominal gap spacing of 0.0028 inch and a sparkover value of 500 peak volts. In order to insure an adequate margin above the sparkover value of the protectors, such equipment was required to withstand a minimum dielectric test of 500 volts rms. In the case of transistorized equipment, however, it is usually not feasible to attain such a withstand level. It has been necessary to develop additional protection measures capable in some instances of limiting potentials to only a few volts.

This paper discusses the source and nature of the foreign potentials hazardous to the dependable operation of communication equipment and the additional protection measures that have been successfully employed to protect relatively delicate equipment of recent design.

Sources of Foreign Potentials

Communication equipment associated with land-transmission facilities both aerial and buried is frequently exposed to abnormal potentials produced by lightning; this, in practice, constitutes the major electrical hazard. Although communication lines and cables frequently occupy pole facilities jointly with power circuits, because of good construction and co-ordination practices, power contacts are relatively few and equipment damage from this source is much less likely than from lightning.

Equipment powered from aerial power distribution facilities in suburban and rural areas is vulnerable to lightning surges entering an installation over the service conductors. Furthermore, failures in rectifiers employing semiconductor diodes have been experienced at times when thunderstorms have not been reported in the general area.

For economic reasons, such equipment is frequently designed to have a relatively small inverse-voltage safety factor; consequently, it has become necessary to consider the effects of switching and other operating transients from the power source. Furthermore, although not within the intended scope of this paper, it is interesting to note that semiconductor diodes employed in power rectifiers, in addition to their vulnerability to foreign potentials, may also be susceptible to damage from internal transients that develop when normal line voltage is applied. This situation should be anticipated by the designer and has recently received some mention in manufacturers' bulletins and published papers.[1]

The exposure of a radio installation to lightning strokes to the antenna is well recognized, and adequate consideration is generally given to the protection of an installation against damage from this source.[2] However, it is not so generally recognized that the probable incidence of strokes to an antenna may in many cases average less than one a year, yet the station equipment will probably be exposed each year to several lightning surges from the power line. Some of these surges may be of sufficient magnitude to cause tower lamp burn out, relay contact burning, and rectifier troubles.

Since the measures employed to protect equipment from foreign potentials on the communication transmission facilities are considerably different from those em-

1959

ployed on the associated power circuits, it will facilitate the discussion to consider them separately.

COMMUNICATION LINES AND CABLES

Lightning surges of sufficient magnitude to be significant from the protection standpoint appear in communication lines and cables as a result of the following.

1. Direct strokes to aerial and buried plant.
2. Exposure of buried plant to earth potential gradients.
3. Exposure of aerial plant to flashover from adjacent facilities and potential rise of associated grounds.
4. Induction in nonshielded facilities.

EXTERNAL POWER FACILITIES

Several years ago rectifier tube and capacitor failures were experienced in power supplies at intermediate telephone-carrier and radio-repeater stations normally receiving their a-c power over aerial distribution lines. Such installations are usually in rural locations and served by small lines having few other users in the immediate area. Lightning surges from the power lines were suspected of being the probable cause of the equipment damage. Although little was or has been done to determine precisely the incidence and characteristics of such surges, the effectiveness of the applied protection measures described later in this paper definitely established the power lines as the source of the trouble. It was incidentally found that after protection was applied to the power service, there was a marked reduction in other equipment troubles, such as lamp burn out in tower warning lights. Rectifiers employing semiconductor diodes may be even more vulnerable to power-line surges than thermionic rectifiers. It is advisable therefore to consider the protection requirements of such equipment during the design stage.

Nature of Lightning Potentials on Communication Lines and Cables

Lightning potentials in communication plant are primarily longitudinal (conductor-to-earth), but metallic voltages (conductor-to-conductor) develop because of circuit unbalances as a result of insulation sparkover or dissimilar operation of some types of protection devices. When there is no circuit path to ground, or such a path is interrupted by a transformer, it is not difficult to provide a minimum insulation withstand level with respect to ground of 700 peak volts; 0.0028-inch protector gaps will in such cases provide adequate protection against longitudinal voltages. However, in circuits having direct paths for the line conductors to ground through components, there may be a problem concerning the ability of these components to conduct currents produced by longitudinal voltages less than the sparkover value of the protectors. In these instances it is frequently possible, by simple design changes, to bring the withstand ability of critical components up to the level where they will be adequately protected by the discharge gaps.

In the more general situation, coupling transformers are used and the circuit elements on the secondary side are exposed only to metallic voltages; however such voltages may reach magnitudes equal to the sparkover value of the higher of the two protector gaps on the primary side of the coupling transformer (500 to 600 peak volts). For low-voltage circuit components which may be damaged by voltages as low as 40 to 50 peak volts, as in the case of transistors, additional protection measures are required.

A lightning surge at or near the stroke point is essentially unidirectional. Such a surge will, however, be modified both in magnitude and waveshape as it propagates through communication lines and cables; consequently it is impossible to anticipate the nature of such surges except in a very general way. Observations on both open wire and cable plant indicate that surges range in waveshape from simple impulses to complex oscillatory transients. These transients vary greatly with the type of plant involved and the operation of associated protection devices. Surges that arrive at a terminal point on a line from a stroke some distance away, or that have otherwise been attenuated so that they will not spark over protector blocks, do not have frequency components as high as commonly supposed. For example, some observations of surges on an open-wire toll line indicated varying amplitude components in the order of 20 kc having durations of 1.0 to 1.5 milliseconds. Metallic transients observed in a loaded cable pair were highly damped and had fundamentals of 1,500 to 2,000 cycles with amplitudes decaying to half value in a millisecond or less.

It was from such data that a 10x600-μsec impulse test wave* was established as suitable for laboratory testing of protection diodes on the basis that such a wave produces equivalent duty on the test specimens. Such a test wave is relatively easy to produce in the laboratory and, through correlation with field experience secured with equipment so tested, provides a satisfactory basis for evaluation of circuits and components.

In one study of foreign metallic voltages on a pair in a metallic sheath cable, 249 surges ranging in amplitude from 40 to 550 peak volts were observed during a total of 10 thunderstorms. The magnitude distribution of these metallic surge voltages is shown in Fig. 1. The upper limit of 550 peak volts was due to the presence of 0.0028-inch protector discharge gaps.

Protection Measures

Protector discharge gaps are the most economical devices available for the initial limitation of both longitudinal and metallic potentials in communication circuits. Such protectors, having nominal gap spacings of 0.0028 inch, are used at subscriber and terminal equipment points with a reasonable amount of protector maintenance. Smaller gap spacings are impractical from a maintenance standpoint; where protection is required below about 600 peak volts, some auxiliary method must be employed. Semiconductor protection diodes have been successfully employed in this lower range. Generally it has been possible to protect transistorized equipment using available voltage-limiting diodes in the range from

Semiconductor Protection Diodes

General Characteristics

Semiconductor diodes have inverse conduction characteristics that make them exceptionally fine voltage limiters. Such devices present a very high resistance when inverse voltages below a critical "avalanche breakdown" value are applied, and also show a well-defined region of substantially constant voltage limitation above this critical breakdown value; see Fig. 2. Although the term "breakdown" is commonly used in referring to the critical voltage range in which a junction changes rapidly from a high-resistance barrier to a good conductor, the term may be somewhat misleading as the phenomenon is not destructive when confined to design limits.

Silicon is preferable to germanium for voltage limiters since it provides a much sharper transition from the high to the low resistance region and will handle more power without a permanent change in characteristics.

Two general types of silicon diodes suitable for protection purposes are now available, the alloy junction[3] and the diffused junction.[4] They have a general similarity in operating characteristics, but the latter type can be more easily produced, having larger effective junction areas. Diffused-junction units are presently available with effective junction dimensions of about 0.125 inch by 0.125 inch, as compared to the alloy types having a maximum effective junction diameter of only about 0.025 inch. For protection applications where the higher capacitance of the larger junction area can be tolerated, the diffused-junction diodes offer distinct advantages. Their greater current-carrying ability and their lower effective resistance result in a smaller increase in voltage above the breakdown value, with increasing surge current as may be noted in Fig. 3. In the application of protection diodes to circuits where surges of both polarities may appear, it is necessary to use two units in series and oppositely poled.

The forward conductivity characteristics of semiconductor junctions may also have application for protection purposes in situations where the normal circuit-voltage levels are very low. A significant change in forward junction resistance occurs in the case of silicon at about 0.5 volt. Although the transition is less sharp than in the inverse direction it may provide sufficiently effective voltage limitation, in spite of the relative softness of the voltage characteristic, because of the very low magnitude at which it starts to limit.

To utilize the forward characteristic in protection applications, it is necessary to employ two oppositely poled junctions in parallel. Such double-unit devices, encapsulated in one envelope similar in appearance to a resistor, have been developed. Because of the nature of the junction material employed there is every indication that they will be very low in cost when in production. In spite of their small physical size, such devices have the ability to conduct surprisingly large values of surge current and have interesting circuit-application possibilities which will be discussed later.

Inverse-Voltage Breakdown Ratings

Protection diodes are rated on the basis of their nominal inverse breakdown value. This rating refers to the small region at the knee of the inverse-voltage current-characteristic curve and is established on the basis of a specific current value, commonly 0.5 milliampere. At present,

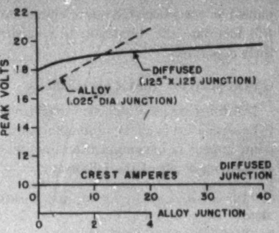

Fig. 3. Voltage-limiting characteristic of typical silicon protection diodes

practical protection diodes can be produced having breakdown ratings ranging from about 6 to 150 volts, direct current.

The response time of a semiconductor diode is extremely fast, in the order of milli μsec. It may therefore be assumed that for protection purposes, the inverse-voltage breakdown point for a lightning surge will be the same as the d-c rated value.

Inverse-Surge-Current Carrying Ability

Semiconductor diodes have a higher resistance in the inverse conducting direction than in the forward direction. Since in most protection applications the diodes are required to conduct current in either direction, their inverse-current carrying ability is the restricting factor in such applications.

Data on inverse current, also referred to as reverse current, given in manufacturers' data sheets generally refer to steady-state direct current and consequently have little relationship to the ability of a diode safely to conduct inter-

Table I. Inverse-Surge-Current Carrying Ability of Silicon Protection Diodes*

Type of Diode	Diameter of Junction, Inches†	Wafer Size‡	Average Breakdown Voltage	Waveshape of Applied Surge, μsec	Withstand Currents (Crest Amperes) Minimum	Median	Maximum

mittent surges or short-duration transients, consequently, valid ratings must be determined by specific tests employing a waveshape comparable to that which the device is likely to experience in the field. For practical reasons, a unipolarity wave is generally employed in such tests and is selected on the basis of equivalent duty. Field experience has indicated that for communication applications, ratings based on a 10x600-μsec wave are reasonably conservative and satisfactory for engineering purposes. (The Western Electric Company plans to include in its published data sheets, information on the inverse-surge-current capabilities of its protection Varistors, generic term used in coding its nonlinear devices.)

Test experience shows that diodes subjected to intermittent surges within their current rating do not appear to suffer any progressive degradation. If failure occurs on moderate overloads, it will be by short-circuiting, which is preferable from a protection standpoint to an open condition. Furthermore, in testing diodes in connection with establishing their duty ratings, tendency to fail will be revealed after only a few applications of a surge of critical value.

The inverse-current carrying ability of a junction is directly proportional to its area and inversely proportional to its breakdown voltage; consequently the higher voltage junctions limited in area to those presently available, 0.125 inch by 0.125 inch, have low-current ratings which restrict their application. However, diodes having lower voltage ratings may be connected in series and thereby meet higher current carrying requirements.

Table I gives the surge-current ratings of several miscellaneous silicon alloy-and silicon diffused-junction protection diodes.

DIODE CAPACITANCE

Protection diodes have capacitance which varies with impressed voltage. Capacitance variations with changes in signal level rarely present a problem in lower frequency applications or when connected at low impedance points in a circuit. In carrier applications, however, the possible effects of capacitance variation should be considered. The theory of diode capacitance is quite complex but an understanding of the general relationships is sufficient for practical purposes. In general, capacitance is directly proportional to junction area and in the inverse direction is inversely related to diode breakdown values. Also the capacitance of a given unit will decrease with the application of inverse bias voltage. These relationships are shown in Fig. 4. In the forward conducting direction, the capacitance of a junction will increase with the application of forward bias voltage. The capacitance of a no. 2052 bipolar unit at 0.0-volt bias is approximately 500 μμf and at 0.35 volt, approximately 600 μμf.

Possible adverse effects of diode capacitance on the functioning of a circuit can be more conclusively determined by test than by the theoretical approach. The development of diodes having significantly lower capacitances is receiving active attention.

BREAKDOWN-TEMPERATURE DEPENDENCE

The inverse-voltage breakdown characteristic of a silicon junction is dependent to some extent on ambient temperature, varying directly at an approximate rate of 1%/10 C (degrees centigrade) Unless otherwise stated it may generally be assumed that the breakdown rating is based on an ambient of 25 C. In protection practice this variation may be neglected since the design margins employed between the normal operating potentials of a system, the breakdown values of the protection diodes, and the withstand ability of the equipment will ordinarily be quite broad in relation to such changes.

PHYSICAL SIZE

Several types of diodes produced for surge protection purposes are shown in Fig. 5. It may be noted that these units do not employ heat sinks as in the case of diodes intended for rectifying applications since the sink would not increase their intermittent-surge-current carrying ability.

Application of Communication Protection Devices

Semiconductor diodes can be arranged to provide both longitudinal and metallic protection. They are chiefly employed, however, for metallic protection since most transmission apparatus is coupled to the line by transformers, which effectively interrupts the longitudinal path. Generally the dielectric strength of the transformers with respect to ground will exceed 600 peak volts, and discharge gaps will provide adequate voltage limitation.

Two simple arrangements utilizing the inverse breakdown characteristics of semiconductor diodes are shown in Figs.

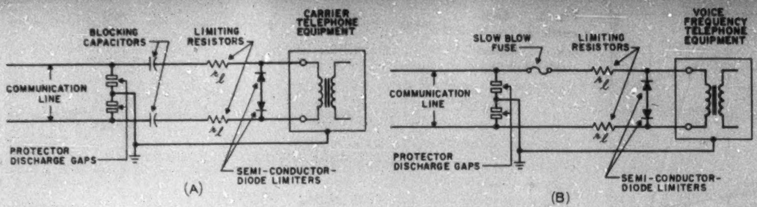

Fig. 6. Protection of low-voltage equipment

A—Carrier equipment
B—Voice-frequency equipment

6(A) and 6(B). Fig. 6(A) could be used to limit metallic voltages appearing at the line terminals of carrier equipment. The limiting resistance r_l is selected to limit surge-current magnitudes to values within the short-duration current capabilities of the diodes. The minimum value of limiting resistance that may be used depends upon diode design and the duration of the current surge. In some applications, resistance values as low as 10 to 20 ohms may be adequate. In carrier applications, a series-blocking capacitor may be used to protect the equipment against 60-cycle power currents if the exposure conditions warrant.

The second, Fig. 6(B) shows a protection arrangement for voice-frequency equipment. The only difference in this case is the substitution of a fuse for the blocking capacitor to protect the diodes against long-duration foreign currents.

In practice it will be found that considerable flexibility in diode application is possible. Since some components, such as line coils, will generally withstand surge voltages up to the operating value of the protector gaps, the diodes need not necessarily be placed at the input to the equipment but may frequently be connected in the circuit closer to the vulnerable components. In so doing, it may be possible to utilize some existing circuit impedance to limit the surge current through the diodes to a value compatible with their rating. Furthermore, it may also be possible, as shown in Fig. 7, to select a diode location having a d-c bias voltage. In this case only a single diode will be required.

An application utilizing only the forward conducting characteristic of silicon diodes for protection purposes is shown in Fig. 8. The maximum normal voice-frequency voltage is assumed to be no greater than about 0.1 volt, in which case a bipolar unit can be employed without adversely affecting system operation. Because of the anticipated low cost of such protector units, it might be economically feasible to employ several such units in series, to allow their application to a higher voltage circuit if the situation requires.

Protection Against Surges From Power Distribution Facilities

The first step in reducing the magnitude of power-line surges entering an installation is by the use of lightning arresters on the secondary service conductors. In this application the preferred location for these arresters is at the service weatherhead, for reasons to be subsequently discussed.

Standard secondary arresters are available having sparkover values in the order of 1,600 peak volts and capable of interrupting the subsequent 60-cycle short-circuit current at secondary voltages up to 175 volts rms to ground. There is a significant protection advantage in securing station service on either a 120-240-volt 3-wire or a 120-208-volt 4-wire basis. Such systems provide a grounded neutral connection for the secondary arresters whereby the potential across the arresters will not exceed their 175-volt rating. The next higher standard arrester is rated 650 volts-to-ground and requires potentials in the order of 2,800 peak volts to initiate sparkover.

Experience has shown that a 175-volt secondary lightning arrester will provide dependable protection for equipment normally considered in the power class such as motors, heaters, lamps, etc. However, such arresters do not fulfill the protection requirements for certain types of communication equipment as previously discussed. Where a high degree of operating reliability is required, it has been found necessary to employ an additional stage of protection in the form of a lower voltage arrester frequently applied to branch circuits serving critical equipment.

This low-voltage arrester is generically the same as any valve-type arrester consisting of a silicon carbide varistor, nonlinear element, in series with a standard carbon protector gap. The varistor element has a minimum resistance at 120 volts rms in the order of 15 ohms to insure interruption of the 60-cycle short-circuit current after surge discharge. Gaps having nominal spacings of 0.0028 inch and 0.006 inch, 500 and 850 peak volts sparkover respectively, have been used, but it is desirable to design equipment capable of co-ordinating with the 0.006-inch gap since it will withstand about four times greater duty than the smaller gap without permanently grounding.

When power voltage regulating devices are employed ahead of critical equipment they frequently introduce sufficient surge attenuation so that the lower voltage arrester is not required.

To insure successful operation of the 2-arrester combination, it is necessary to have regulating impedance between the two units. This insures operation of the higher voltage secondary arrester which limits discharge current through the lower voltage arrester, thereby preventing the arrester discharge voltage from exceeding the initial sparkover value of the gaps and insuring satisfactory gap life. Although a discrete impedance could be inserted between the two lightning arresters for this purpose, it is the practice to utilize the impedance offered by wiring run in steel enclosures. In Bell System installations, steel service conduit is employed. In order to secure its maximum benefit, the secondary arresters are located at the

weatherhead. Laboratory tests and field experience show that a 20-foot conduit run will give satisfactory results. Since 20 feet is about the minimum length normally used in our installations, the low-voltage arresters may be located in the area of the service cabinets if desired. However, these low-voltage arresters are frequently placed in the equipment cabinets to secure the benefit of longer wire runs.

Two principal methods of application are used. In installations where there is spare equipment with provision for automatic switching of units, or where the rectifiers are of the trickle type and the equipment in turn operates from a battery the arresters are placed directly on branch circuits as shown in Fig. 9(A). In such cases the branch-circuit overcurrent protection device may be allowed to operate if an arrester should become permanently grounded. In situations where service continuity is not assured by the means mentioned above, the arrester circuits are provided with their own alarmed disconnect devices as shown in Fig. 9(B) to avoid de-energization of the equipment.

The use of a disconnecting device in series with the lightning arrester has the disadvantage of leaving the equipment unprotected during the time required to service the arrester, however, the situation involves a compromise and it has been assumed that the exposure of the equipment during this period constitutes less risk of service interruption than from the operation of a circuit fuse or breaker caused by a permanently grounded arrester bridged directly on the circuit.

Three Decades of Progress in Electrical Insulation

L. J. BERBERICH
FELLOW AIEE

Synopsis: The last 30 years cover a period marked by outstanding advances in certain areas of electrical insulation. This period begins with what might be termed the synthetic-chemical age and ends with the beginning of the space age. Specifically, the paper records briefly the progress made in the theoretical phase of the field, the development of new insulating materials, the revision of the electrical insulation temperature standards, and the application of insulating materials to power equipment. The progress made in the development of materials, many of which were unheard of 30 years ago, has been truly phenomenal. This has resulted in marked advances in the design of new equipment. A few of these advances in the power field are discussed. Progress made in insulation temperature standards has resulted in new revolutionary methods of rating insulating materials and systems of materials as used in electric equipment. This has enabled the electrical industry to take better advantage of the host of new synthetic materials developed during the period covered by this review. This period may be characterized as one in which research and development in the insulation-materials area has, in a marked way, stimulated radical advances in design, reliability, and performance of electrical equipment. No radically new advances were made in the theoretical phase of the field, but the gradual progress made in the underlying theories has contributed considerably to our understanding of dielectric phenomena, especially in the liquid- and solid-state areas.

IT HAS BEEN SAID that the creation of a new product or the improvement of an existing one must be preceded by an advance in the materials which go into the making of these products. This statement is particularly true of the electrical manufacturing industry in general, which thrives on change directed toward progress. More specifically, it is particularly true of electrical insulation, since much of the progress made by the industry can be traced to advances made in the electrical insulating-materials field. For example, the motors, transformers, and other electrical components now being developed for operation at temperatures up to 500 C (degrees centigrade) for use in high-speed military aircraft, would be impossible without the recent progress made in inorganic insulating materials.

Paper 59-75, recommended by the AIEE Electrical Insulation Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, February 1–6, 1959. Manuscript submitted October 20, 1958; made available for printing November 20, 1958.

L. J. Berberich is with the Westinghouse Electric International Company, East Pittsburgh, Pa.

The author wishes to acknowledge the assistance of his associates in the Westinghouse Electric Corporation. He also wishes to thank Joseph Sticher of the Detroit Edison Company for supplying some material on power cables.

The electrical manufacturing industry is characterized by converting such raw materials as steel, copper, aluminum, plastics, paper, and textiles into a large variety of finished products. Wholly new products, such as magnetic amplifiers, nuclear reactors, semiconductor devices, fluorescent and electroluminescent lamps, and many other electric appliances unknown 30 years ago, have been created. Even such basic electrical products as the generator, the motor, and the transformer have been improved markedly in efficiency, reliability, and appearance. Some of these have been so improved in performance and appearance that the present product bears little resemblance to its counterpart of 30 years ago. This dynamic mood of the electrical industry is stimulated in part by an aggressive research and development policy, particularly in the materials field, in which an important place has always been assigned to electrical insulation.

Further evidence of progress in the electrical industry is manifested in its phenomenally high rate of growth. During the last 3 decades, this growth has averaged about 10% per year. The magnitude of the growth can be better appreciated when this is compared with 3% annual increase of our gross national product. Besides the normal factors which stimulate growth, such as increase in population, there is the almost insatiable demand for electric power-consuming devices. This demand is being greatly stimulated by the continual reduction in cost, as well as improvement in reliability and performance of these devices. In all of these, the progress made in the field of electrical insulation has played an important if not commanding role.

The period covered by this review was selected for several reasons. It covers the time of the writer's research and development experience in this field; it marks the most remarkable progress in the electrical insulation area; AIEE showed increasing awareness of the importance of this field, leading to the formation of the Electrical Insulation Committee (EIC). The writer has served as chairman of this committee.

The EIC now has eight very active subcommittees. It recently organized and sponsored jointly with the National Electrical Manufacturers Association, the first National Conference on Electrical Insulation Application. It is expected that this conference will be an annual affair, and plans are underway for the 1959 conference to be held in Washington. While electrical insulation has received some considerable attention in the AIEE in the past through subcommittees associated with the various apparatus committees, it is only in the last few years that the unifying influence of a separate technical committee on electrical insulation has already made itself felt in generating more rapid progress in this important field.

The existence of a full technical committee on electrical insulation within the AIEE does not deny the importance of the various apparatus insulation subcommittees. As in the past, they still will treat important insulation problems related to the insulation systems as used in various types of electric equipment. In contrast, the EIC will treat the field of electrical insulation broadly, ranging from theory to general applications, the latter especially when more than one line of apparatus is involved. Neither does the existence of this committee in the AIEE deny the importance of the excellent work done in other technical organizations. This is especially true of the National Research Council Conference on Electrical Insulation, Committee D-9 on Insulating Materials of the American Society for Testing Materials, the Electrical Insulation Division of the Electrochemical Society, and a similar group in the American Ceramic Society. These groups treat the more basic chemical and physical aspects of the field, and supplement rather than duplicate the work of the AIEE committee and the various insulation subcommittees attached to the apparatus committees. All of these groups were founded either during or shortly before the beginning of the period under discussion.

To review in detail the progress made in this field during the last 30 years would require considerably more space than is available. Hence, this treatment of the subject will be limited to brief discussions of progress made in the theoretical phase of the field, the insulating-materials area, the insulation temperature standards area, and the application to various kinds of power equipment, such as transformers, rotating machinery, power capacitors, etc. While this review will thus be limited and also influenced by the writer's own background of experience, it is hoped nevertheless that a reasonable, though much abbreviated, picture of progress in this important area is presented.

Progress in Theoretical Area

Most of the early work on the behavior of dielectrics in electric fields was carried out by physicists. The contribution of such illustrious physicists as Cavendish, Faraday, and Maxwell are well known. Since the beginning of this century, however, most physicists have deserted the field of electrical insulation for other more glamorous fields, such as electron or atomic physics, X-ray structure, quantum mechanics, solid-state physics, and more recently nuclear physics. Thus, during the early part of the period under consideration there were relatively few physicists working in the field. Some of the more prominent of these are J. B. Whitehead (deceased), S. Whitehead (deceased), A. von Hippel, K. W. Wagner, W. Jackson, H. Fröhlich, P. Debye, L. B. Loeb, and others. Well before the beginning of this period, Maxwell had developed his theory of dielectric absorption or interfacial polarization (1875); Paschen had announced his law relating electrical breakdown of a gas and the product of pressure and electrode separation (1889); Townsend had developed his ionization-by-collision theory of breakdown in gases (1900); Debye had published his paper on his theory of polar molecules (1912); Wagner had announced his thermal breakdown theory for solids (1922); and the fields of quantum and wave mechanics were being created with the publication by Schroedinger of the wave equation (1926). No radically new theory was developed during the period, but other new developments in the fields of physics and chemistry did much to improve our understanding of dielectric phenomena, especially in the solid- and liquid-state areas.

Important contributions to our understanding of conduction, polarization, and electrical breakdown in dielectrics were made during the last 30-year period, however. While Faraday, Maxwell, and others were familiar with the fact that in insulators, in contrast to metals, electrons were not free to move except in a restricted manner, a clear explanation of the difference in conduction between metals and insulators did not develop until the advent of quantum mechanics in the early 1930's. According to this theory,[1] the valence electrons of both metals and insulators are arranged in energy-level bands, with the important difference that in insulators the conduction band is filled with electrons whereas in metals it is only partly filled. Thus, when a small voltage is applied to a metal, the energy of the valence electrons is easily raised and conduction is possible in the unfilled band. In insulators, on the other hand, electronic conduction does not easily take place because of the presence of a relatively large

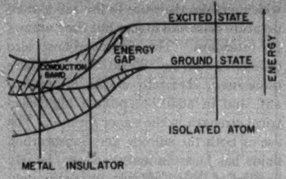

Fig. 1. Energy-band picture for metals and insulators compared with that for isolated atom

forbidden-energy band immediately above the filled conduction band. Considerable voltage, essentially the equivalent of breakdown voltage, must therefore be applied to insulators to cause electrons to bridge this region in large numbers. Most of the conduction observed in insulators at voltages well below electrical breakdown, therefore, has been observed to be ionic in nature rather than electronic. The energy-level picture illustrating schematically the difference between metals and insulators is shown in Fig. 1.

Semiconductors lie intermediate between metals and insulators and the conduction may be either electronic or ionic, depending on the nature of the semiconductor and the temperature. As a matter of fact, the whole body of knowledge developed in the field of solid-state physics which led to the development of such devices as the solid-state rectifier, the transistor, dynistor, etc., has added considerably to our understanding of conduction in insulating solids.

Knowledge of conduction and electrical breakdown in gases, in particular, has been improved through extension of Townsend's theory and study of Paschen's law[2,3] during the period. Also, it was discovered that certain gases, particularly those containing the electronegative elements of chlorine, fluorine, and bromine possess considerably higher electrical strengths than nitrogen or other similar gases. This has been ascribed to the ability of electronegative elements to capture electrons during the early stages of the breakdown process, thus making necessary the application of a high voltage to reach breakdown.[3,4,5] Sulfur hexafluoride, SF_6, and perfluorobutane, C_4F_{10}, are examples of such electronegative gases.

As a result of work done by von Hippel,[6] Fröhlich, and others, our knowledge of breakdown in solids, and to lesser extent in liquids, has been improved appreciably during the period. It appears that all breakdown in the final stages involves the formation of electron avalanches but that the processes leading to the final stages in solids and liquids differ from the simple ionization-by-collision process which applies for gases. It was also learned that breakdown in solids, in particular, is decreased by increase in temperature either through externally applied heat or internally generated heat caused by losses.[7] There are some who believe that there are two mechanisms of breakdown[8] in solids, namely: 1. electronic, which is substantially independent of temperature, and 2. thermal, which decreases linearly with temperature on a log-breakdown voltage, versus reciprocal of the absolute-temperature plot.

Much more, however, needs to be done before we completely understand breakdown in solids, and especially in liquids. In the case of liquids, in particular, many factors enter such field emission, electrode effects which handicap the investigator. Despite these difficulties, some recent careful work on hydrocarbon liquids[9] indicates that the electrical strength is a linear function of density of the liquid and also that molecular structure has an important effect on electrical strength.

Much also has been learned during this period about polarization and conduction in solids. Faraday had observed, many years ago, that when a fixed direct voltage is suddenly applied to an insulator, the current decreases with time and finally reaches a finite fixed value. It is now known that this current in the generalized case is made up of a number of components. These are as follows: 1. Electronic polarization current, which is caused by an elastic displacement of the electrons with respect to the nuclei of the atoms constituting the material. All materials show this type of polarization. 2. Ionic polarization current, which is caused by an elastic shift of atoms themselves with respect to each other and occurs especially in cases where atoms of different types form molecules in a solid. In these cases the electrons of the two or more dissimilar atoms are not shared uniformly. This effect occurs in crystals like KCl, and is particularly pronounced in a ferroelectric material such as barium titanate, whose dielectric constant is very high for this reason. 3. Orientation or dipole polarization current, which is caused by the orientation of permanent dipolar molecules in the direction of the field. An example of this is found in the cellulosic paper in which hydroxyl groups (OH) form a permanent dipole with respect to carbon atom to which they are attached and hence rotate when a field is applied. More than half of the dielectric constant of the cellulose fiber is contributed by this mechanism. 4. Interfacial or space-charge polarization current, which is caused by charge carriers or ions which can move only a limited distance or become trapped at interfaces of the various components of an inhomogeneous dielectric. Most solids show this effect in varying degrees, and under alternating voltage it produces contribution to both losses and dielectric constant. 5. Final constant conduction current, which is caused by ions migrating more or less unimpeded through the dielectric and contributes only to the losses and not to dielectric constant under alternating voltages.

All of these components go to make up the charging current when alternating voltage is applied to a capacitor in which a generalized material showing all of these mechanisms of polarization is the dielectric. The first two are generally considered instantaneous polarizations in the sense that they can respond, if present, to frequencies of 10^{12} cps (cycles per second) or higher. The next two seldom are observed at frequencies above 10^8 cps, and in many cases do not respond at much lower frequencies. The last, of course, is not a polarization current, therefore, does not contribute to the dielectric constant but produces losses over the whole frequency range.

It should be pointed out that during the period a considerable number of physical chemists have worked in this field. Among the better known might be mentioned Kirkwood, Debye, Symth, Onsager, and Fuoss. These and many others have made very valuable contributions in relating chemical structure to dielectric properties, especially in respect to dielectric constant and loss behavior. This type of information has been valuable in the development of new dielectrics, particularly for capacitor, cable, and other applications.

Engineers were also engaged in this area of research. They were especially concerned with refining the various theories developed by the physicists and physical chemists and applying their findings to the solution of practical problems. As was pointed out in 1940,[10] and it is equally true now, progress in this field is due to the combined efforts of physicists, chemists, and engineers, the "triple alliance in electrical insulation."

This brief review of the theoretical aspects of the field may be summed up by saying that no radically new theory has been developed during the period and that steady progress has been made in improving our understanding of dielectric phenomena. It is also pointed out that our knowledge in the insulation area has been considerably enhanced through advances in related fields, particularly in solid-state physics and chemistry. Marked contributions were also made through relation of structure to dielectric properties.[11] Many challenging problems remain to be solved especially in the electrical strength and conduction areas. A more extensive review of this phase of the subject is given by von Hippel in reference 3.

Progress in the Materials Area

The progresss made in creating new materials during this period has been truly remarkable. The fact that the period began with what might be called the synthetic age has already been mentioned. It is in this area that organic chemists, working not only in chemical industry but also in the electrical industry, have played a stellar role. In the early 1920's organic chemists were almost unheard of in electrical research and development laboratories. They, however, began to appear in increasing numbers in the early 1930's. The result of their work, and particularly of those in the chemical industry, has been an almost continual stream of new materials which might be called the products of synthetic chemistry. They have largely replaced the natural materials in common use in the early days of the electrical industry. Even though in some cases new synthetic materials with the desired electrical properties were developed in the electrical industry, the chemical industry must be credited with the major contribution, particularly in the plastics and elastomers areas.

In order to obtain a better picture of the progress made over the last 30 years, it may be of interest to examine lists of the more important categories of materials available in 1928 as compared with those available now. The following tabulations contain such lists in much abbreviated form.

Gaseous Materials. Table I shows that the most important new addition to the list of gaseous materials in the last 30 years center around fluorine containing compounds known as electronegative gases. Only several of the available gases of this type are listed. The principal advantage of these over ordinary gases is higher electrical strength by a factor of two or more at the same pressure.[3,4,5,12] Increasing interest is being developed in these gases for uses in special gas-filled transformers and to some extent in capacitors. Sulfur hexafluoride more recently has been found to possess the additional advantage of high arc-interrupting ability compared with air and other gases. This combined with high electrical strength has resulted in its use in a new line of circuit breakers.[12] The use of hydrogen in 3,600-rpm turbine-generators as a cooling and insulating medium was initiated at the beginning of the period, and it continues to be used, at higher pressures and with greater effectiveness. The principal advantages of hydrogen in this application are better heat transfer and lower windage losses. Its electrical strength unfortunately is about 60% that of air at the same pressure.[13]

Table I. Progress on Gaseous Materials

1928	1958

Table II. Progress in Fluid Materials

1928	1958
Rosin oil	Petroleum oil
Castor oil	Chlorinated hydrocarbon fluids
Petroleum oil	Diester fluids
	Silicone fluids
	Fluorocarbon fluids

Fluid Materials. Table II shows that petroleum oil is the only important fluid in use at the beginning of the period that is still in use now. This low cost fluid, which has been much improved during the period,[3,14] still is the most common fluid used in high-voltage transformers, circuit breakers, and oil-impregnated paper cables, and to a small extent in capacitors. Rosin oil and castor oil are no longer being used to any appreciable extent and have been replaced by the synthetic fluids, especially in capacitors. The chlorinated fluids, known by the generic name of "askarel" and developed in the early 1930's,[15] possess fire-retardant properties and have more than twice the dielectric constant of petroleum. This has enabled them to find extensive use in power capacitors and to a limited extent in transformers requiring a fire-retardant fluid. The diester fluids have been useful in high-frequency (10^5 and 10^6 cps) capacitors.

The silicone fluids,[3] developed during World War II, possess thermal stability which enables their use to the 180 C temperature class and higher but they are not fire-retardant. The fluorocarbons, also developed during World War II, are quite inert, thermally stable, fire-retardant, and in addition, possess high electrical strength in the vapor form.[3,4] The use of both the silicone and fluorocarbon fluids has been limited, however, largely because of their high cost, approximately 100 and 300 times the cost of an equal volume of petroleum oil, respectively. It should be pointed out, however, that part of the reason for the higher cost, particularly in the case of the fluorocarbon fluids, is because they are still only in pilot production. The askarels first introduced over 25 years ago are made in large quantities and sell at from five to eight times cost of an equal volume of petroleum oil.

Papers and Textiles. Table III shows that a considerable number of additions have been made during the period to the list of the familar cellulosic and asbestos papers and fabrics. Cellulose, however, in the form of paper, pressboard, cotton fibers and fabrics, is still most important in this category from a volume standpoint. The materials based on cellulose combine low cost with excellent electrical, chemical, and physical properties. They, however, have the disadvantages of being sensitive to moisture and of being limited thermally to the 105 C temperature class.

It is this thermal limitation, as well as sensitivity to moisture, that stimulated the development of the inorganic-fiber papers and more recently organic-synthetic-fiber papers and fabrics. The former are satisfactory for use to at least the 180 C temperature class. Usually, however, their temperature rating is determined by the resinous binder used with them. The more important examples of these are the glass-fiber fabrics, mica paper, and glass-fiber paper. The synthetic organic papers are still in the pilot-production stages although most of the same fibers, such as nylon (polyamide), Dacron (polyethylene terephthalate), and Orlon (polyacrylonitrile) have been produced in large volume in the form

Table III. Progress in Papers and Textiles

1928	1958

	Inorganic papers

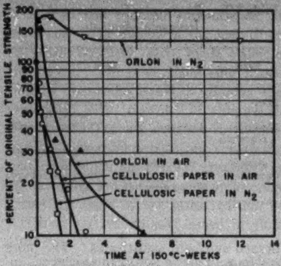

Fig. 2. Effect of aging at 150 C on cellulosic paper and synthetic acrylonitrile (Orlon)

of fibers for use in woven fabrics. The high cost and the lack of voltage-barrier action in these and all other fabrics have, however, seriously limited their use as insulating materials. The chemical and paper industries are now learning how to make papers from the synthetic fibers which promise to have at least some voltage-barrier action and considerably lower cost than their woven counterparts. This should result in numerous applications when they become available in production quantities at a reasonably low price. The thermal-stability data of Fig. 2 comparing Orlon fibers with cellulosic paper show that the former should have considerable advantage over the latter, especially if sealed away from air.

Resins and Varnishes. This is an area where synthetic materials have made very considerable inroads on the formerly used natural materials, such as rosin, natural gums, shellac, and asphalt as shown in Table IV. This class of material has found extensive use as adhesives, binders, varnishes, impregnants, and casting molding and laminating resins. Some are also used in the form of extrusions, especially on wires and cables.

Table IV. Progress in Resins and Varnishes

1928	1958	
Rosin	Shellac	Polyester resins
Natural gums	Asphalt	Polyvinyl chloride
Coal tar pitches	Vegetable drying oils	Epoxy resins
Shellac	Phenolic resins	Methyl methacrylate
Asphalt	Alkyd resins	Melamine
Vegetable drying oils	Polystyrene	Polyamide resins
Phenolic resins	Polyethylene	Polyurethane resins
	Polyethylene terephthalate	Silicone resins
	Cellulosic resins	Fluorocarbon resins

Of particular importance is the development of a number of resins, specifically the polyesters, epoxies, and certain silicones, which are fluid in the unreacted form, thus requiring no solvents. These are completely heat-reactive and do not evolve volatile by-products while reacting to the solid state. This enables their use in many casting and impregnating applications where obtaining void-free structures is important. No resins of this type were available as early as 1935 and all were developed within the last 20 years.

Perhaps of even greater importance is that some of these resins have enabled operation of electrical equipment at higher temperatures than the original 105 C and 130 C classes, classes *A* and *B*, respectively. As a matter of fact, the present AIEE 180 C temperature class, class *H*, was originally designed around the silicone materials which were developed during World War II. The fluorocarbon resins, also developed during World War II, meet the requirements of this temperature class from a thermal-stability standpoint, but have not been applied as widely as the silicones in electrical equipment because of higher cost and difficult processing. However, where outstanding inertness and solvent resistance are special requirements the fluorocarbons have no equal.

The organic chemist has been expending considerable effort in the area of tailoring resin molecules to meet special requirements. Thus, the industry now has available fire-retardant resins (polyvinyl chloride), arc-resistant resins (melamine, methacrylates, some alkyds, and ureas), and thermally stable resins (silicones and fluorocarbons). It is in this area that molecular engineering, or designing molecules for particular applications, is meeting with considerable success and more is expected in the future.

Wire Enamels. The wire-enamel field is one in which the chemist practices molecular engineering to a high degree. The thin film placed on copper or aluminum wire must meet extemely rigid requirements of flexibility, toughness, solvent resistance, and electrical strength. Table V shows that in 1928 only one type of wire enamel made from natural resins was available. The first synthetic wire enamel was developed in the late 1930's by the General Electric Company.[16] It was found that, on reacting a polyvinyl formal resin developed by Shawinigan Chemical Company with a phenolic resin, an enamel with considerably better properties than those of the older oleoresinous enamels resulted. Other synthetic enamels soon followed, and in the last 10 years a considerable number of new ones were developed with even better properties, especially in respect to thermal stability. The curves of Fig. 3, giving the lives of the various types of enamels as a function of temperature, show the progress that has been made in respect to thermal stability. These curves were developed by an AIEE working group on enameled magnet wire,[16] which currently is very active in developing test procedures for determining the thermal rating of film-coated magnet wire. The data of Fig. 3 are for enamels with no varnish treatment. Some of these enamels show even greater lives when treated with compatible varnishes, and data on varnished enameled magnet wire are also included in the report of the AIEE Working Group.[17]

Table V. Progress in Wire Enamels

Oleoresinous	Oleoresinous	Polyesteramide
	Polyamide	Polyester-epoxy
	Polyvinylformal	Polyester
	Epoxy	Modified silicone
		Polyurethane

Elastomeric Materials. This is another area where the organic chemist has made remarkable progress. Table VI shows that only several materials, namely natural rubber and gutta percha, were available in 1928 and that all of the various synthetic rubbers have since been developed.[8] Work was being done on synthetic rubbers in Germany in the 1920's, but not much progress was made in this country until the late 1930's when it became apparent that our source of natural rubber supply might be jeopardized by the impending World War II.

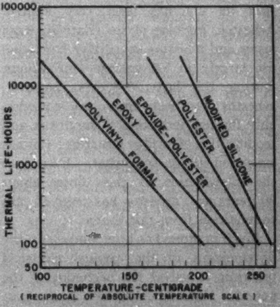

Fig. 3. AIEE No. 57 twist-test results on various classes of unvarnished wire enamels

Table VI. Progress in Elastomeric Materials

1928	1958, Rubber	
Natural rubber	Natural.......	Butyl
Gutta percha	Neoprene.....	Polyester
	Buna-N.......	Silicone
	GR-S..........	Fluorocarbon

The exception of this was neoprene which was first synthesized at Notre Dame University in the early 1930's and then developed commercially by Du Pont.

Some of the synthetic rubbers listed were developed in Germany but a good proportion of them, particularly butyl, silicone, polyester, and fluorocarbon rubbers were developed in this country. While most of the elastomers listed are limited to the 105 C temperature class, the silicone rubbers in particular have been found to meet the requirements of the 180 C temperature class. Perhaps the single most important application of synthetic rubbers in the electrical-insulation area is the insulated wire and cable field.

Ceramic and Other Inorganics. Table VII lists only the major classes of materials of this type. Again it is seen that a considerable number of wholly new materials have been developed in the last 30 years. The ceramist and the inorganic chemist working with engineers have been responsible for progress in this area.[3,18] Mica, asbestos, electrical porcelain, certain electrical glasses, and cements have been used almost from the beginning of the electrical industry. Mica, in particular, has such a unique combination of properties that it has been found to be almost indispensible for the insulation of commutators and coils for the larger sizes of rotating machines. Only in recent years has mica been produced synthetically, and then only with such small flake size that its use has been very limited. Asbestos, because of its relatively high losses and moisture sensitivity has found use largely in low-voltage applications. During the last 20 years, however, asbestos has been improved considerably through reduction of impurities and modification of its fiber structure; this has expanded its use somewhat. Ever since the introduction of glass fibers about 20 years ago, asbestos has received stiff competition from this source.

Much progress has been made since the development of the original electrical porcelain in use at the beginning of the period. Not only has this early porcelain been improved but wholly new compositions, such as zircon and alumina porcelains, have been developed.[3] Too frequently it was not realized that the early electrical porcelains were not very satisfactory at temperatures much above 100 C because of their high conductivity brought about by a high-alkali-metal content. The zircon and alumina porcelains were developed for higher temperature applications and in general have low-alkali-metal contents. The latter, for example, has found extensive use in aircraft engine spark plugs, where mica used to be the only satisfactory material. Zircon porcelains, as is the case with electrical steatite, possess low losses and hence have found use in high-frequency applications.

Many new glass compositions have also been developed during the period. Those with low losses and the desired physical properties have made possible the development of the vacuum tube art as we know it today. In this connection the Corning Glass Company has played a leading role.[19]

Perhaps the most startling development in this area concerns the titanate ceramics. It has been known for many years that TiO_2 in the rutile crystalline form possesses a dielectric constant of the order of 100.[20] It was not until the early 1940's, however, that it was discovered by Wainer and associates,[21] then with the Titanium Alloy Manufacturing Division of National Lead Company, that certain titanates possess even higher dielectric constants. Values of dielectric constants of over 5,000 have been reported for barium titanate and combinations of barium and strontium titanates. Commercial compositions which have found applications in the electronic capacitor field usually consist of barium titanate with minor additions of other materials to flatten out the sharp peak in the dielectric constant versus temperature curve. The titanates also have found application in the ultrasonic field as transducers after it was discovered that they could be polarized to produce piezoelectric properties.[3]

This brief review of new materials developed during the period may be summarized by saying that outstanding progress has been made. A host of synthetic materials have appeared which have replaced many of the natural materials once used in the electrical insulation area.

Many of these materials have made possible remarkable advances in equipment design, some of which will be illustrated in the last section of this paper. A few natural materials, however, are still being extensively used because of their unique combination of properties and difficulty of economically creating improved synthetic substitutes. The more important of these are mica, petroleum oil, and cellulosic paper. Only small progress has been made in developing improved synthetic replacements for materials of this type but work now going on in the development of synthetic-organic-fiber papers appears very encouraging.

Progress in Insulation Temperature Standards Area

The problem of rating electrical equipment, and the influence of the thermal stability of materials on the rating, has been under periodic review for many years. AIEE No. *1* was the first formal document published by the AIEE and it may be best described as a guide to the preparation of insulating material and equipment temperature rating standards. Even though it was revised several times during the period under discussion no very radical changes from the 1930 edition were made until the appearance of the 1957 edition.[22] The revolutionary changes made in this latest edition were brought about by the appearance of the multitude of new synthetic materials discussed in the previous section. These newer materials could not be properly classified thermally under the old system.[23]

Under the former system, materials were placed into various temperature classes, according to whether they were organic or inorganic, or a combination of these two broad chemical classifications. Since the silicones did not fit into either of these two classifications, a new temperature class, 180 C, was added in 1947 when these important materials were finding increasing number of applications in the insulation field. A real dilemma, however, was created when it was found that an increasing number of the new synthetic organic materials possessed thermal stability comparable to that expected of combinations of inorganic and organic materials. More recently, some have even been developed which approach the silicones in this respect. This made it almost mandatory to develop a new ap-

Vol.
Pt. 1
1959

proach to the thermal classification of materials. The events of the last 10 or 15 years, therefore, have made obsolete the former system of classifying materials by definitions based on whether the materials were organic or inorganic. This turn of events resulted in a completely new philosophy of classifying materials which has evolved gradually in the last 20 years.[24] This new philosophy forms the basis of the latest edition of AIEE No. *1*, which was issued in June 1957.[23]

The beginning of the new philosophy of insulation classification dates back to the period, when Montsinger[25] and others tried to relate the effect of time and temperature to the properties, or more particularly to the life, of insulating materials. This soon led to the well-known "8-degree rule" for oil-impregnated transformer insulation, which states that the rate of deterioration is doubled for every 8 C rise of temperature. Expressed in another manner, this means that the life of transformer insulation is halved for every 8 degree rise in temperature. This important finding, though only approximately true, was soon applied to the loading of transformers when it was recognized that a short-time overload would not destroy the transformer, but merely reduce the normal life by an amount which could be computed from the temperature and time duration of the overload. The procedure was later extended to other apparatus although not covered by formal standards.

This rule-of-thumb relationship between life of insulation and temperature was used in varying ways until the late 1940's. It was then found, as the chemist had long since known, that the chemical-reaction-rate theory as exemplified by the classic Arrhenius equation may be applied to insulation aging. If it is postulated that insulation deterioration approximates a first order chemical-reaction rate, as has been shown to be true in many cases, the Arrhenius equation may be expressed as follows:

$$\text{Deterioration rate} = A\epsilon^{-B/T} \qquad (1)$$

or, since life L is reciprocally related to the rate of deterioration, life may be expressed as

$$\text{Life} = L = A'\epsilon^{B/T} \qquad (2)$$

which may be converted to the logarithmic form, or

$$\text{Log } L = \text{Log } A' + B/T \qquad (3)$$

where T is the absolute temperature, A, A' and B are constants determined by the activation energy of the particular reaction, the gas constant, and the concentration of the reacting materials. Thus, equation 3 indicates that if the logarithm of the life of insulation is plotted against the reciprocal of the absolute temperature, a straight line should result.

This relationship was confirmed, with few exceptions, by data obtained on many materials. It was found, for example, that when the logarithm of the life of chlorinated diphenyl-impregnated paper capacitors is plotted against the reciprocal of the absolute temperature, almost perfect straight lines resulted.[26] The exceptions were found when the second and higher order reaction rates enter into aging phenomenon which sometime take place at the higher temperatures. Extensive application of reaction-rate theory to insulation deterioration was not made until relatively recently. This was further stimulated by two important general papers on this subject, the first by Dakin[27] which appeared in this country in 1948, and the second by Mamlow[28] which appeared in Sweden in 1949. These two papers thoroughly review the principles upon which the Arrhenius equation is based and show how they apply to the analysis of insulation-deterioration data.

In the last few years these principles have been incorporated into accelerated life tests which have formed the basis of procedures for determining the thermal rating of materials[29,30] and systems of materials as they are used in various types of electric equipment.[31–35] These procedures all require the obtaining of aging data under prescribed conditions and plotting the statistically analyzed data on a log life versus reciprocal of the absolute-temperature plot. Then, if it is established that the data form approximate straight lines on this type of plot, as often is the case, the line may be extrapolated with caution to a generally accepted standard life value and the corresponding temperature rating may be read from the plot. Thus, the approximate rule-of-thumb relations, having no scientific basis, have now been almost entirely replaced by the more accurate relation based on the classic Arrhenius equation. It has also been realized only recently that the temperature-rise interval over which the insulation life is halved is not a constant, but increases with the temperature for a given material, provided a single reaction-rate law is obeyed over the whole temperature range.

The very considerable interest in this field is not limited to this country, but a similar interest has been generated on a world-wide basis by the International Electrotechnical Commission (IEC). This world standardizing body has also engaged in a review of its insulation temperature standards.[36] The wording of the definitions of various insulation temperature classes in IEC Publication 85 are very similar to those in AIEE No. *1*, illustrating the important role played in world standards by the AIEE.

The revised insulation-temperature standards now permit the electrical industry to take better advantage of the many new synthetic materials with improved thermal stability, such as the wire enamels in Fig. 3. To implement the new philosophy of insulation classification, a test procedure for each major class of material will be required, as well as a test procedure for each of the various insulation systems as they are used in electrical equipment. The work of developing these test procedures is well started, but much more remains to be done to complete this monumental task. The progress made so far, however, can be recorded as a major advance in this very important area of the electrical field. One of the more important by-products of this work is marked advance in our understanding of the mechanism of thermal deterioration of various types of materials.

Applications to Power Equipment

Reference was made earlier to the fact that much of the progress made in electrical apparatus can be attributed to advances made in electrical insulation. It will be the purpose in this section to cite a few examples of such progress in the rotating-machinery, transformer power-capacitor, and cable fields.

Rotating Machinery. In the case of the smaller 105 C class *A* machines, the more important insulating materials at the beginning of the period under review were cotton as conductor insulation, paper as slot liners or coil wrappers, and varnished cambric or untreated cotton tapes as coil insulation. The whole motor was treated in a oleoresinous or asphaltic type of varnish. With the advent of synthetic materials in the last 10 years or more, most of the cotton-covered wire has been replaced with enameled wire and part of paper slot liners and coil insulation has been replaced with synthetic films, such as Mylar (polyethylene terephthalate). The whole machine is treated with a synthetic varnish and then baked at an elevated temperature. Fig. 4 shows the improvement in motor life made possible by improvements in wire enamels and varnishes. The data were obtained from motor tests conducted according to AIEE

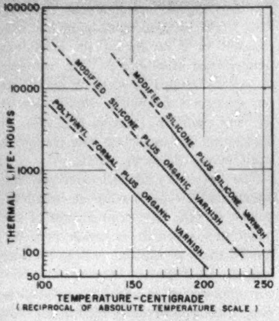

Fig. 4. AIEE No. 510 motor-life-test results on various wire enamel-varnish combinations

No. *510* random-wound motor-insulation test procedure. It is apparent from Fig. 4 that the newer modified silicone enameled wire-varnish combinations should be satisfactory for operation at 130 C class *B*, and possibly higher temperatures. The polyvinyl formal-organic varnish combination has been used since about 1940 as 105 C temperature class insulation and serves as a basis for comparison.

Mica tapes and wrappers have been used for many years in the larger motors designed for 130 C class *B* operation. Mica, however, had to be bonded with organic varnishes and this limited the use of this combination to the 130 C temperature class. With the advent of silicone varnishes, glass-fiber tapes, and glass-fiber-covered conductors, a new insulation-temperature class was created, namely the 180 C class, class *H*. Fig. 5 shows the size reduction possible in 7.5-hp (horsepower) 3-phase motor by the application of the 180 C class materials over the normal 105 C class materials. All of the 180 C class materials were developed during the period under review. More recently, some organic materials have been developed with improved thermal stability and this appears to make possible their use at temperatures above the 130 C class. For this reason, a new temperature class, namely the 155 C class, class F, was added to the 1957 edition of AIEE No. *1*. This permits the use of materials at 155 C maximum hottest-spot temperature, or higher if they meet the requirements of this temperature class by standard test or performance.

Improvements in the large power-generating units, particularly the steam-turbine-driven generators, have been even more startling. This has manifested itself in the ever increasing kva rating of the units being built. Fig. 6 shows that the maximum available kva rating in 1928 was less than 50,000 and now units approaching 500,000 kva are being built. It is true that much of the progress in this area is the result of improved cooling efficiency, but improvements in insulation also played a very important role. The use of hydrogen as cooling gas started at the beginning of the period under discussion, and marked improvements in cooling efficiency have been made by gradually raising the pressure, and more recently, by going to the inner-cooled design. In the latter, hydrogen is circulated through tubes in close thermal contact with the copper conductors of the coils, thus very effectively shortening the path for the heat produced by I^2R (current resistance) losses in the copper.

The insulation used in the stator coils of both the large turbine-generator units as well as water-wheel-generator units has been based on mica since almost the beginning of the electric power industry. The first binder used with mica flakes was shellac, but at the beginning of the period under discussion petroleum asphalts came into the picture. The latter resulted in a more flexible insulation which could be applied continuously in tape form.

In the last 15 years, however, it became apparent that as the machines became larger, the asphalt binder has some limitations, both electrically and mechanically. Since asphalt is very viscous, even when heated, it is difficult to impregnate into the coil structure to fill all of the void spaces. Also, since asphalt may be looked upon as a viscous liquid even at ordinary temperatures, this material allowed insulation movement during operation of the machine as a result of temperature cycles. It became apparent as early as 1940 that a better material than asphalt for use as a mica bond must be found and therefore active work was carried on with the increasing number of synthetic resins appearing even at that time.

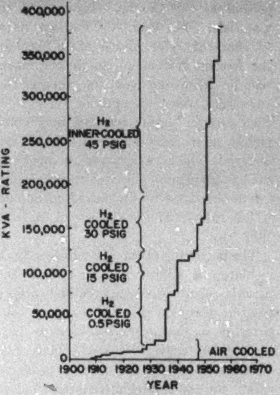

Fig. 6. Maximum available kva rating of 3,600-rpm turbine-generators

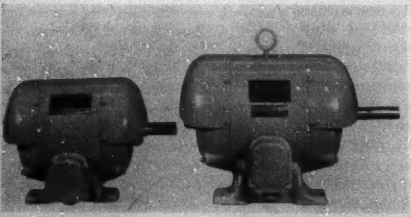

Fig. 5. Size comparison of a 7.5-hp 440-volt, 3-phase class H motor (left), and a class A motor of the same rating

After some 10 years of work with synthetic-resin-impregnating media and the development of radically different processing methods that were required, the first new synthetic resin bonded and impregnated mica insulation for large turbine-generators was announced in 1950 by Westinghouse Electric Corporation. The account of this development was published in the 1951 AIEE *Transactions*.[37] This insulation is based on the use of completely heat reactive synthetic resins which are applied in the fluid state and subsequently polymerized after they are in place. This insulation, called Thermalastic, has since been applied to water-wheel generators as well as to motors and generators in the integral hp class. Improved electrical and physical properties have enabled this insulation to achieve an outstanding record in the 8 years since its introduction. But more important, it has enabled the construction of larger and more efficient generating units with added assurance that insulation will perform more satisfactorily. The improved voltage endurance behavior of the new insulation compared with the old asphalt bonded type is illustrated in Fig. 7. A photograph of one of the first turbine-generators

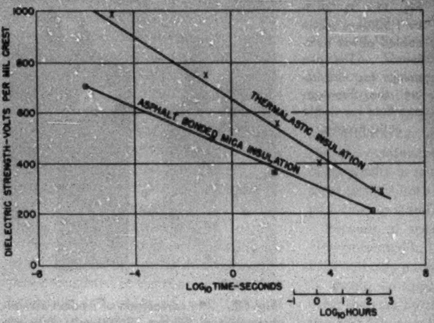

Fig. 7 (above). Dielectic strength and voltage-endurance behavior of the old and new generator-insulation systems

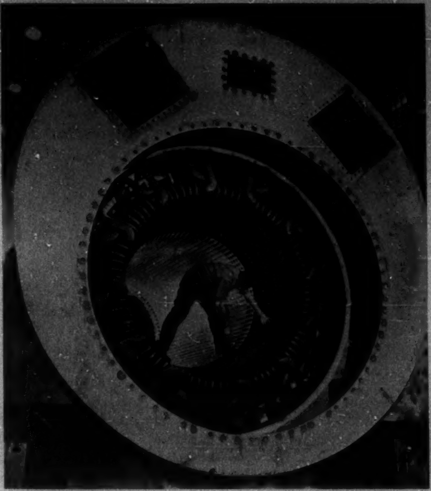

Fig. 8 (right). Hydrogen-cooled turbine-generator showing Thermalastic coils in place

constructed with Thermalastic insulation is shown in Fig. 8.

Progress is continually being made in rotating-machinery insulation and periodic announcements of new insulation systems have been made, particularly in the last few years. Among the more important of these are an all-silicone rubber insulation for motors and generators known as Silco-Flex, announced by Allis-Chalmers in 1955,[38] and a synthetic-resin bonded-mica paper insulation for large generators announced by the General Electric Company in 1958. The properties of the latter insulation, referred to as Micapal, has been described in reference 39. These few examples should serve to illustrate that insulation developments played an important role in bringing about progress in the rotating-machinery field. Some of this progress is reviewed in several relatively recent books on this subject.[40,41]

Transformers. As with rotating machinery, the progress made in transformers was to a marked degree influenced by insulation developments. In the distribution transformer area the use of enameled wire in place of cotton- or paper-covered wire, together with improvements in oil and magnetic steel, has resulted in a significant size reduction for a given rating. Fig. 9 shows photographs of one of the first type CSP 5-kva transformers, built in 1935, compared with similar 15-kva units built recently. In the lower voltage rated instrument transformers there is a trend away from the taped and asphalt-impregnated structures to resin embedded and molded units. Filled epoxy resins are finding application in cast units; there is considerable interest in the use of butyl, polyester, and silicone rubbers in molded units. Since some of these compounds have excellent weather resistance, it has been possible to replace the earlier asphalt-impregnated units with molded or cast units even for outdoor applications. In some of these the metal case and porcelain bushings were eliminated. The use of butyl rubber in this type of application was first announced in 1955.[42] A polyester rubber developed within the last few years has found considerable application in molded indoor-current transformers. Fig. 10 shows a series of the new polyester-rubber molded units, with the older units which they replaced immediately behind them.[43]

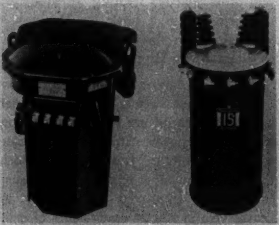

Fig. 9. Comparison of a 1935 model, 5-kva CSP-type transformer (left), and a 1958 model, 15-kva CSP-type transformer

The advent of silicones has enabled the design of smaller, more compact dry-type power and network transformers. In these units the more important materials used are fiber-glass conductor insulation, ceramic-coil spacers, and glass-mica barrier tubes. The whole unit is impregnated in silicone varnish. Prior to the introduction of silicones, no dry-type units for operation above approximately 150 C were available. Now temperature ratings have been increased to 200 C and higher.

In liquid-filled transformers, progress of a different type has been made. As in 1928, the most important insulating materials used in this type of transformer are still petroleum oil and two cellulosic products, namely, paper and pressboard. Despite considerable effort, no economically feasible synthetic equivalents of these materials have been developed. Improvements, however, have been made in both the oil and cellulosic products. These, combined with improvements in magnetic steel and cooling efficiency, have enabled the construction of units rated up to 400,000 kva. These improvements have brought about very marked reduc-

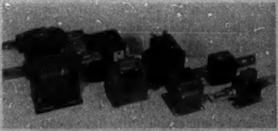

Fig. 10. New polyester rubber molded current transformers (front row), with their older counterparts

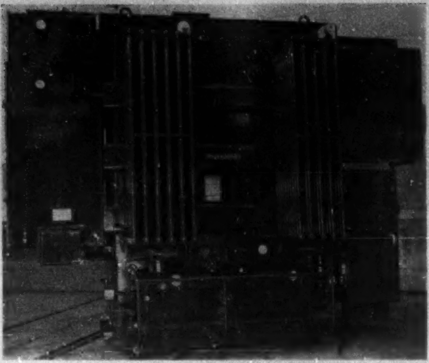

Fig. 11. A 34.5-kv 7,500-kva vapor-cooled power transformer. The two pumps for circulating the fluorocarbon fluid are visible at the bottom

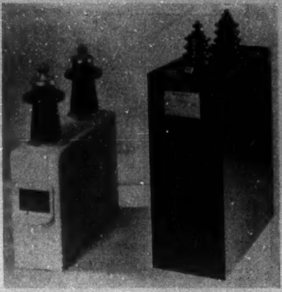

Fig. 12. Size comparison of modern askarel-impregnated 10-kva 2,400-volt 60-cycle capacitor (left), and old oil-impregnated capacitor of the same rating

tion in weight per kva as well as physical size for a given rating. This latter is important, particularly since the maximum rating that can be built is not determined by the manufacturing limitations, but by the facility with which the unit can be transported to the site of application.

With the advent of the electronegative gases in the 1940's, considerable thought has been given to applying them to transformers. With the higher electrical strength values obtainable with these gases than with air or nitrogen at the same pressure, it appeared that transformers should be an ideal application. While a specialized application of sulfur hexafluoride, SF_6, in high-voltage X-ray transformers was announced by General Electric in the 1940's, further large scale application of electronegative gases in transformers has been slow. This perhaps is because of the many problems involved in their use, not the least of which is cooling. With the development of the fluorocarbon gases and liquids during the latter part of World War II,[3,4] however, a new concept of transformer cooling and insulating was developed. This involved the spraying of an inert, fire-retardant fluorocarbon fluid on the core and coil structure, thus utilizing the heat of vaporization in cooling the transformer and at the same time making use of the high electrical strength of the electronegative fluorocarbon vapor.[4,5] The first experimental model of this transformer was constructed in 1951 and announcement of the vaporization-cooled design was made by Westinghouse at that time.[44] Several commercial units have been built, the first of which rated at 15 kv and 500 kva, has been in successful operation for more than a year. The second unit, rated at 34.5 kv and 7,500 kva, is shown in Fig. 11. Others are in the design stages.

Interest in gas- and vaporization-cooled transformers continues at a high level. A number of manufacturers are developing new design information. Several units rated at 2,000 kva and 69 kv based on the use of sulfur hexafluoride gas are under development by the General Electric Company.[45] Other gas- and vapor-cooled units of even higher rating are certain to follow. This is a striking example of how the development of new insulating materials has made possible radically new equipment design.

Power Capacitors. At the beginning of the period under review, power capacitors were constructed with cellulosic paper impregnated with a petroleum oil as the dielectric. During the period, as mentioned previously, the askarel liquids[15] which consist of chlorinated aromatic hydrocarbons, were made available. These materials, developed and produced by the Monsanto Chemical Company and its predecessors, have excellent electrical properties for this application. Of particular importance is the fact that their dielectric constant is about twice that of petroleum oil. These liquids first came into use in the early 1930's and gradually replaced petroleum oil as a power-capacitor impregnant almost completely by 1940.[15] By virtue of the fact that the dielectric constant is higher and closely approaches that of the cellulose fiber in paper than is the case for petroleum oil, the askarels have made possible a marked size reduction. This is shown in Fig. 12, which gives a size comparison between an old oil-impregnated unit and a modern askarel-impregnated unit of the same rating.

While cellulosic paper is still used in power capacitors, considerable improvements in electrical strength and dielectric losses have been made in the last 30 years. This, combined with use of askarel instead of oil, has made a possible operation of the capacitor dielectric at stresses up to 400 volts per mil, 60-cycle alternating current, and over 1,000 volts per mil direct current. In addition, lower losses have enabled the construction and satisfactory operation of units rated at 100 kva. This should be compared with a maximum rating of about 15 kva available in 1928.

The application of askarel to capacitors is a striking example where the use of a synthetic material with a cost of five or six times that of the petroleum oil it replaced, has resulted in lower over-all cost of the finished unit. Since the volume of the capacitor for a given rating has been reduced to one half that of the older, oil-impregnated unit, not only is half as much liquid required but also only one half as much paper, aluminum foil, steel for the container, etc. The net result is a more reliable unit which can be marketed at an economic price. These and other matters relating to capacitors are reviewed in a book by Marbury.[46] Capacitors are also discussed in several chapters in von Hippel's relatively recent book.[3]

High-Voltage Cables. Cellulosic paper and petroleum oil are still being used in high-voltage power cables as is the case with high-voltage transformers. Both the oil and the paper have, however, been considerably improved in the last 30 years. No synthetic equivalents of cellulose paper and petroleum oil have yet been found which combined low cost and the electrical properties required in high-

Vol.
Pt. 1
1959

voltage power cables. Plastics, such as polyethylene and butyl rubber, however, have made inroads in the medium-voltage power cables rated up to about 15 kv. Experimental installations of polyethylene-insulated power cables rated at 34 kv have been made recently. Polyvinyl chloride and rubbers of various types have been used for some time in low-voltage cables and insulated conductors. All of the plastic materials and rubbers, except for natural rubber, were developed during the period under review.

The most important breakthrough in the high-voltage cable area during the period consisted of the control of internal ionization by means of new types of cable designs. Just a little over 30 years ago, the so-called oil-filled Pirelli-type cable was developed in Italy, which enabled operation of cables up to 132 kv as early as 1927. In contrast the older solid-type cable could not be operated satisfactorily above about 69 kv. This was accomplished by use of oil channels in the cable and associated expansible oil reservoirs together with a freely flowing oil at all cable-operating temperatures.

Later, a number of other new cable designs were developed such as the self-contained compression types, the pipe-types in which the cable is kept under pressure by use of either gas or a liquid, and the gas-filled types. This has resulted in cables which are now operating in this country at voltages up to 230 kv. An experimental field installation is planned for 1959 at Cornell University to study cable designs for eventual use in the 300- to 400-kv range.

In summary, progress in cables for high-voltage power applications is not characterized by the use of radically new materials. Significant improvements, however, have been made in both the paper and oil properties and even more so in cable designs. Plastics and synthetic rubbers have almost entirely replaced natural rubber and varnished cambric formerly used in medium- and low-voltage cables. Progress in this, as with the other fields discussed in this paper, are recorded in the AIEE and other technical literature. Some of the problems encountered in the cable field have been reviewed in von Hippel's recent book.[3]

Summary

The outstanding progress made in the field of electrical insulation over the last 30 years may be summarized as follows: 1. The refinement of the theories which has resulted in a better understanding of dielectric phenomena. 2. The development of an imposing array of new synthetic materials which have replaced many of the natural materials formerly used. 3. The development of a new philosophy of thermally rating insulating materials and systems of materials as they are used in electrical equipment. 4. The application of the new materials in electric equipment in a manner which often results in major advances in equipment designs both from an economic and performance standpoint.

Because of space limitations the review presented in this paper is necessarily brief and only a few examples can be cited. It should be apparent from these, however, that the record of achievement over the past 30 years is an imposing one. It was undoubtedly accelerated through the co-operative efforts of physicists, engineers and chemists. The future looks even more promising. With the coming of the space age, insulation for electric equipment to operate at 500 C and higher in high-speed aircraft and rockets is already under development. The all-inorganic systems now being developed show considerable promise of finding applications other than in the military categories.

A considerable number of references are cited in this review, but these are far from complete. For a more complete reference to the literature in this field, the reader is referred to the "Digest of Literature on Dielectrics."[47] The National Research Council Conference on Electrical Insulation has performed a most valuable service in issuing this digest on an annual basis for more than 20 years.

Remotely Controlled Electroluminescent Totaling Display

A. LEGER
NONMEMBER AIEE

THE NEED for automatic visual display of numerical information has grown rapidly in recent years. As a result, at least a dozen different numerical indicators are now available. Each will show any one of the ten Arabic numerals when actuated by the proper pattern of electrical signals. Some show painted numerals by electromechanical means; others use optical projection, masked lamps, edge-lighted plastic sheets, matrices of incandescent or neon lamps, numerically shaped wires in neon lamps, or cathode-ray tubes to indicate the desired numerals. Some distribute the ten numerals along a vertical line; some stack the numerals in depth, and some show each and every numeral in the same space and on the same plane. The device described here uses an electroluminescent phosphor to form a truly planar numerical indicator.

The applications for these numerical indicators are many, but they can be grouped conveniently into two classes. The first class contains numerical indicators used as substitutes for "scale and pointer" indicators in the meter and instrument field. Digital voltmeters, for example, are being used more and more frequently in laboratory and production measurements. The advantages of numerical display include better readability with no interpolation, parallax, or scale-factor errors, and more efficient use of panel-board area (a 2-digit indicator needs far less front panel area than a good 1% meter). The second class of applications concerns the replacement of manual posting of tabular data by automatic numerical display boards. This class is illustrated by the plans of several stock-exchange associations for automation of their entire operation, including the BID and ASK display boards, and by the military's requests for automatic numerical display boards to replace their chalk or grease pencil-on-acetate STATUS and ACTION boards. One advantage of automatic displays is faster and more accurate posting of changes in situation.

Most of the present automatic numerical display boards, which are typical of the second class of applications, use electromechanical indicators of the rotating belt or cylinder type. This paper describes a digital-display system of that class. However, it uses a new kind of solid-state indicator, an electroluminescent (EL) device,[1] for the display of numerical and symbolic information. The accompanying circuitry is composed of solid-state elements throughout. Thus the entire system is static; it is compact, requires low power, and offers high reliability.

Description of the System

Fig. 1 shows the digital-display system which is the subject of this paper. Such a system could be used by the dispatcher of a fleet of trucks, for example, to keep track of the availability and activity of his trucks, stationed at a distant location. The toggle-switch unit on the left of Figs. 1(A) and (B) would be located remotely, requiring only the single pair of wires running to the dispatcher's office. Each position on the display would correspond to a particular truck and would show if it was ready for assignment. The display would also show the total number of trucks available at that time.

The system has two functions: it reproduces the input information on the display board, and it summarizes that information. The encoding unit on the left in Fig. 1 has nine toggle-switch inputs and accompanying pilot lamps. The decoding unit receives the input information over the single pair of wires and controls the adjacent EL-display unit. The display unit shows the toggle-switch positions by a column of nine ON-OFF symbols (letter *A*s), and also shows the total number of ON switches

---

Paper 59-69, recommended by the AIEE Solid State Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted October 10, 1958; made available for printing November 28, 1958.

The authors wish to acknowledge the contributions by Dr. R. L. Bright to the synthesis of the system and the design of many of the transistor circuits.

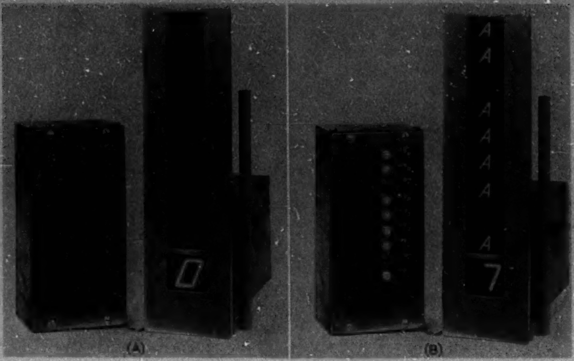

Fig. 1. Digital display system

by a numerical indicator at the base of the column. Because this device was intended primarily to illustrate the use of EL indicators, and not for installation in a particular system, only one short column was constructed. By direct expansion of the circuitry and display panel, a multicolumn board could readily be built; by simple extension of the method, the columns could each consist of many numerical indicators rather than ON–OFF (binary) indicators, with a multidigit summary at the base of each column.

In the paragraphs that follow, the construction of the display board, the operation of the system, and some of the circuits used will be described.

Construction of the Display Board

The binary and numerical indicators used in this system are self-luminous, using the phenomena of electroluminescence as their source of light. Just as visible light can be produced by exciting certain phosphors with ultraviolet radiation (photoluminescence) or with an electron beam (cathodoluminescence), so also visible light can be produced by exciting certain phosphors with an alternating electric field (electroluminescence).[2] Fig. 2 shows the construction of such an EL plate. The phosphor is mixed with a plastic dielectric and is sandwiched between a glass plate on one side and a metallic coating on the other side. The glass plate has a conductive but transparent coating on the side adjacent to the dielectric. The metallic coating is currently an evaporated layer of aluminum. If an alternating voltage is applied between the conductive transparent coating and the metallic layer of this "condenser," light is generated and will radiate through the glass plate.

PHOSPHOR-PLASTIC LAYER
GLASS PLATE WITH TRANSPARENT CONDUCTIVE COATING
LIGHTING PANEL
SYMBOL PANEL
NUMERAL PANEL

Fig. 2. Electroluminescent plate construction, back view

For the display of symbols and numerals, the back electrode is evaporated through a stencil, with the results shown in the lower left and right parts of Fig. 2. The letter *A* symbols are excited by applying an alternating voltage between the conductive transparent coating and the segments forming the desired *A*. As is now apparent, the symbol *A* used in this system is an arbitrary choice; any symbol or set of symbols adaptable to stenciling could be used. As an alternative to the ON–OFF *A* symbol, the system could have used a double symbol such as *HK*, showing *H* for the switch ON and *K* for the switch OFF. A thin colored sheet of plastic, having good transmission in the blue and green wavelengths only, placed in front of the EL plate is especially desirable. It offers marked improvement in the contrast between the excited segments and the surrounding background.

The pattern used to show each of the ten Arabic numerals in the same area requires nine separate segments, as shown at the lower right of Fig. 2. Fig. 3 shows how excitation of the proper EL segments can show all ten numerals in easily recognizable form. The segment pattern shown evolved from a basic 7-segment figure-8 pattern and is only one of several possible elaborations.

The advantages of this type of self-luminous numerical and symbolic indicator are many. Some are related to the solid-state nature of electroluminescence. It requires no evacuated envelope or heated filament. As a result, the possibility of a catastrophic failure, as is common with incandescent lamps, is exceedingly small. This feature is of special importance where numerals are formed by many separately lighted segments; failure of a single segment can result in misreading some numerals. Because the EL plate is thin (essentially the thickness of the glass), it forms a truly planar indicator and therefore is readable over an exceedingly wide viewing angle. As a result of the method of construction, the plates can be made in a wide range of sizes and the numerals could range from several feet to a fraction of an inch in height. This use of electroluminescence has an additional advantage over the use of other light sources. Because it is an area source of light, and because only the desired shape need be excited, all the light generated is useful, none is wasted. Although projection systems may have comparable total light efficiency (expressed in lumens per watt), they require reflectors, lenses, and masks to form numerals and symbols. As a result, only a fraction of their total light output is available at the front of the indicator. For the same brightness of indication projection devices will dissipate much more heat than the EL area source, and heat is an important consideration in a large display board. Brightness of present EL indicators is sufficient for operation in adequately illuminated rooms. Future advantages include the

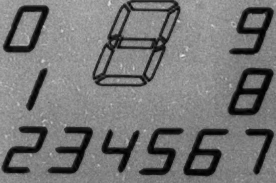

Fig. 3. Nine-segment numeral pattern

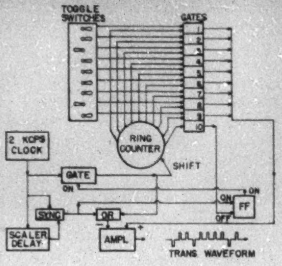

Fig. 4. Control and encoding circuit

property of change in emitted color with change in excitation frequency.

Description of System Operation

In this system, information is transmitted from the encoding unit to the decoding unit and display board over a single pair of wires in a series of pulse bursts. Each pulse burst contains the entire information to be displayed, making the system highly redundant. However, this results in rapid error correction should the information be garbled in transmission. The pulse bursts are obtained by sweeping the input circuit and interrogating each switch. If the switch is ON, a positive pulse results; if the switch is OFF, a negative pulse is generated. Although the system described here is entirely binary, decimal information may be encoded in a binary code, thus the binary design is not a system limitation. When the pulse burst is received at the decoding unit, the first pulse (which is always negative) resets the entire display to its OFF or zero state, as shown in Fig. 1(A). A counter then sums the positive pulses in the burst and causes the total to be displayed. The pulses are also distributed to memory circuits where the positive pulses cause the proper *A* symbols to be excited.

Fig. 4 shows the block diagram of the circuitry used to obtain the pulse bursts. To describe the operation of the circuitry, the flip-flop is assumed to be initially ON. The clock runs at a 2,000-cps (cycles per second) rate. Because the flip-flop is ON, the clock gate conducts pulses to the ring counter, causing it to successively actuate each of the ten gate circuits. If a particular toggle switch is thrown OFF, no pulse will be generated at the corresponding gate when the ring counter actuates that gate. Hence, the only pulse appearing at the output amplifier will be the clock pulse conducted through the clock gate and the OR circuit. It will cause a negative-output pulse to be transmitted. If a toggle switch is thrown ON, the coincidence of the ring counter and toggle-switch signals will generate a pulse at the respective gate. This pulse goes to the positive input of the amplifier and, by inhibiting the clock pulse appearing at the negative input, causes a positive-output pulse to be transmitted. This operation continues until the ring counter has scanned all nine switches and reaches the tenth gate. It then turns the flip-flop OFF, thus disabling the clock gate, and ending the transmitted pulse burst.

Clock pulses are also used to drive a scaler delay, which sets the repetition rate of pulse bursts. The scaler has a capacity of about 50 counts; it generates an output pulse, resets, and begins scaling again after each 50th clock pulse. Because its output pulse comes just after the clock pulse, it is synchronized with the next clock pulse. It starts the transmission of another pulse burst by causing a negative pulse to be transmitted and by turning the flip-flop ON again. The flip-flop then opens the clock gate and the ring counter again scans the input switches, beginning on the next clock pulse. Circuit element delays are sufficient to prevent this operation from occurring at the same clock pulse. The negative pulse is followed, therefore, by nine information pulses. The burst repetition rate is 1/50th of the clock frequency, i.e., 40 cps.

The decoding and display circuitry is shown in Fig. 5. The first incoming pulse of the burst, being negative, triggers the monostable multivibrator. This in turn resets the ring counter, the summation counter, and the memory flip-flops, and also blanks the numerical display for the duration of the pulse burst. The remaining nine incoming pulses serve three purposes: 1. They are rectified and used to drive this ring counter synchronously with the encoding ring counter. 2. The positive pulses appear at the gate circuits and the coincidence of any positive pulse with its corresponding ring-counter output produces an output pulse at the respective gate. This output pulse turns the flip-flop ON and the *A* symbol corresponding to the proper toggle switch is excited by the control circuit. 3. The positive pulses also appear at the summation counter where they are totaled. The state of the counter is translated to the required 9-segment code and actuates control of the numerical display. This translation is accomplished by an AND–OR diode matrix. Because the output of the translation matrix indicates zero when the summation counter is reset and then indicates each successive number as the counter totals the positive pulses, the display is blanked until the transmission is completed. The blanking is not readily noticeable because the burst repetition rate is 40 cps, and because the transmission lasts only one-fifth of the 25-millisecond repetition period.

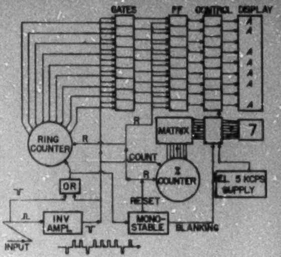

Fig. 5. Decoding and totaling circuit

Although a pair of wires are used for transmission in this system, a single channel of any kind, having sufficient bandwidth to pass the pulse bursts, would serve equally well. Slower transmission rates would permit transmission over narrower bandwidth channels. Applications suggested by these comments include binary, numerical, or symbolic indicators for supervisory control and other telemetry systems. The manually operated toggle switches of this system could be replaced by any type of automatic switching device. The decoding and display unit could serve as a special purpose output device for a digital computer, provided the proper pulse pattern could be generated.

Description of the Circuitry

Because the circuit used for control of the EL segments was designed especially for this application, and has not been described elsewhere in the literature, it is described in some detail in the following. The scaler-delay circuit combines magnetic cores with transistors and is explained briefly. The counters and the translation matrix are also described. The rest of the circuits used in this system are essentially standard transistor-circuit designs and are not included in this paper.

All the circuits for this system are constructed on etched cards, for economy of space and convenience of assembly. The advantage of this method is illustrated by the following example. Nine flip-

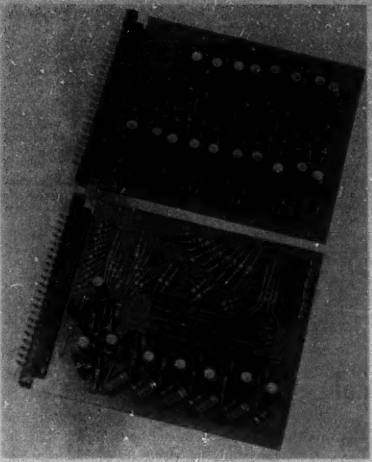

Fig. 6 (left). Flip-flop and ring counter cards

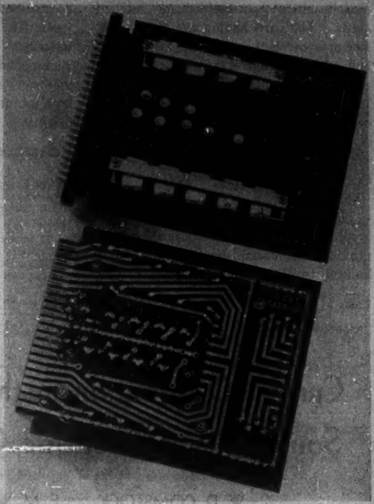

Fig. 8 (right). Electroluminescent-display control circuit card

flops are required to store the states of the *A* symbols. They require 18 transistors, which are all assembled on one 4-by-5-inch 22-contact card. Fig. 6 shows the component sides of that card, and a ring counter-with-gates card. A total of three cards are used for the encoding circuitry, and six cards for the decoding and totaling circuitry.

Counter Circuits

The same circuit is used for both ring counters and for the summation counter. A 10- or 9-state device is required in each case. The circuit departs from common practice in that a flip-flop driving a ring of five is used rather than a ring of ten or a 4-stage binary counter. A ring of ten requires ten transistors and places rather stringent requirements on them because each base must couple to the other nine collectors. The flip-flop and ring-of-five combination uses only eight transistors, including a buffer between the flip-flop and the ring circuit. As a result, each of the nine gates in the encoding and the decoding units is a 3-input diode AND, having a switch or transmission input, an input from one side of the flip-flop, and an input from one stage of the ring counter. Coincidence of pairs of the last two inputs determines each of the ten states.

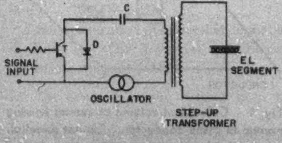

Fig. 7. Electroluminescent-display control circuit

Translation Matrix

Another result of using the flip-flop and ring-of-five combination is that translation from the state of the summation counter to the 9-segment code is neither straight binary nor decimal. The method of Karnaugh Maps[3,4] was adapted to fit this unusual input code and was used to minimize the number of diodes required in the AND–OR matrix.

Scaler Delay

Rectangular loop magnetic cores and switching transistors are combined in the scaler-delay circuit. The scale factor of about 50 is accomplished by one pulse-generator core and one counting core, together with three transistors. The circuitry is similar to that described at the 1955 National Electronics Conference[5] and in other references.[6,7] It makes use of the high-remanence flux of such magnetic materials.

Display Control Circuit

The electroluminescence described in this paper is an alternating-field phenomenon. Typical operation for display purposes is at a frequency of 400 cps and an alternating potential of 230 volts rms. Some means of control is needed to gate this high-frequency high-voltage power to the EL segments in response to the low direct-voltage logic signals. A single transistor a-c switch was developed for this purpose. Such a switch has three basic requirements; it must pass current efficiently in either direction when closed, it must block voltage of either polarity when open, and it must have a good ON to OFF resistance ratio. Most junction transistors can pass current efficiently in only one direction and can block voltage effectively from only one direction. By adding a shunt diode from collector to emitter, and a capacitor in series with this transistor-diode combination, all requirements of an a-c switch are met; see Fig. 7. When the transistor is biased ON, currents from emitter to collector pass through the transistor while currents from collector to emitter pass through the diode. The capacitor, if properly chosen with respect to the load, will offer negligible impedance. When biased OFF, the transistor and diode both block during the half cycle when the instantaneous polarity is positive at the emitter. On opposite half cycles, the capacitor charges through the diode to the peak value of the supply voltage and no further current flows. Although the transistor and diode must each block twice the peak supply voltage, the load current is divided between the two. The step-up transformer is required because presently available transistors do not have the necessary voltage rating. Fig. 8 shows these a-c switch circuits assembled on etched cards. The card having the component side up controls the numerical display and has only eight control circuits. Although the display is composed of nine segments, Fig. 3 shows that one segment is always ON and hence does not require active control.

Conclusions

The most important feature of this system is the use of electroluminescence to provide the visual display. It is not limited to the circuitry here described nor to the few applications mentioned before. The marked advantages of EL numerical and symbolic indicators include: solid-state construction, wide-angle viewing, wide range of size and shape, high useful luminous efficiency, and good brightness.

Current Distribution in the Cylindrical Source Plane-Electrode Configuration

W. D. COMSTOCK
ASSOCIATE MEMBER AIEE

E. M. WILLIAMS
MEMBER AIEE

THERE ARE a number of instances in the operation of electric apparatus in which the physical situation may be approximated by a configuration in which a plane electrode conducts current which is received from or delivered to a cylindrical conducting path normal to its surface. Among these instances the most familiar examples are cases in which the conducting path is an ionized column resulting from sparkover (breakdown) of a solid, liquid, or gaseous dielectric between conductors, or the process of arc formation by the separation of initially juxtaposed conducting surfaces between which current is flowing. Typical situations correspond to circumstances accompanying insulation failures in apparatus, relay contact "breaks," circuit-breaker operations, and to the sparkover phenomena utilized in electric spark machining.[1,2] In each of these situations craters are formed on the electrode surface. Considerable attention[3–5] has been given to the phenomena of crater formation for obvious reasons. Formation of the craters has been attributed to various causes[1,5,6] and, indeed, the predominant cause may vary, depending on conditions of current formation, duration and magnitude, and on current-density distribution in the ionized column. In at least one range of physically realizable circumstances current density beneath the surface has been demonstrated[3] to be significant in determining the depth of crater formed by a particular discharge. The relationship demonstrated was of a qualitative character only, however, owing to the lack of quantitative knowledge concerning both transient and steady-state subsurface current distribution. This paper describes the results of an analytical study of current distribution under appropriate conditions. In this study steady-state current distribution was determined from work by others on an analogous problem in hydrodynamics.[7,8] Transient current distribution was determined by a solution which is described in some detail in the Appendix.

The problem of interest was reduced to the following:

> A cylindrical current column of uniform current density instantly starts flowing, normal to the surface of a plane conductor. The diameter of the column is assumed constant. What is the current distribution beneath the surface of the conductor and how does it vary with time?

The solution of this problem in the form stated should be of direct value in the study of electrode phenomena following sparkover in gas dielectrics, in which the discharge cross section is believed to remain relatively constant as a function of time. However, in liquid dielectrics the discharge cross section increases in area approximately linearly with time over a wide range of time duration[3] during a transient interval before quasi-stable pressure and temperature conditions are reached. Nevertheless, in the time interval in which area is increasing the solution of the above problem can be used advantageously to estimate the conditions under which skin-effect will be important. Moreover this solution should apply well to the relatively long duration (in terms of the time intervals in which skin-effect is important) discharges in the circuit breaker.

It should be recognized that the progressive formation of enlarging craters at the termini of an actual discharge would modify the physical situation in a way that is not taken into account by the analytical model suggested. Owing to

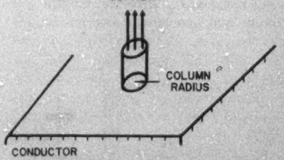

Fig. 1. Cylindrical column of current flowing normal to plane conductor. Current direction may be either into or out from conductor; mathematical analysis based on the latter

the present absence of knowledge concerning the dynamics of formation of such craters this difficulty is unavoidable. However in the discussion of the results of this investigation it will appear that this solution nevertheless permits some deduction as to the rate of crater formation.

The configuration of interest is depicted in Fig. 1. The following additional conditions are postulated:

1. The diameter of the current path is constant.

2. The current density in the current column is uniform throughout its cross-section. This is actually not the case except, possibly, for an initial condition following sparkover, but no information is available as to actual transient current-density distribution.

3. The current is established instantaneously at an initial value which is sustained throughout the period of interest. Actually a finite time interval is required for establishment of current in sparkover cases; during this interval current rises and voltage falls. For very short gaps this interval is known[3] to be of the order of 20 millimicroseconds (mμs). Certainly, as far as microsecond and longer phenomena are concerned the duration of the initial interval may be neglected.

A mathematical model of the physical situation is depicted in Fig. 2. It comprises a source of uniform current density acting over a circular area on the surface of an infinite half-plane of conducting material.

The process of analytical solution is summarized in the Appendix. The resulting computed characteristics of the current distribution are described by normalized radial and axial components of the current density, $J_r' = J_r/J$ and $J_z' = J_z/J$ respectively, as functions of the normalized space parameters, $z' = z/r_0$ and $r' = r/r_0$, and the normalized time parameter, $t/\mu\sigma r_0^2$. J_r and J_z are actual current densities and J is the current density in the discharge column. The depth below surface is z, r is radial distance from center of current column, r_0 is radius of current column, t is time in seconds after initiation of the current, μ is meter-kilogram-second (mks) magnetic permeability of conductor, and σ is (mks) electrical conductivity of conductor.

The physical nature of the results is illustrated in Fig. 3. Three ranges of τ are defined as: $\tau < 0.01$, extreme skin-effect range; $0.01 < \tau < 1.0$, intermediate skin-effect range; and $\tau > 1.0$, steady-state range.

Results of considerable generality are obtained as a consequence of the use of normalized quantities. In the extreme skin-effect range, the radial component of current density is given by the simple asymptotic expressions of equations 14 (A) and 14(B). Typical values of J_r' for $\tau = 0.01$ are plotted in Fig. 4. Axial current densities, on the z axis, which amounts to an extension of the axis of the discharge, are given by expressions of equations 15(A) and 15(B) and are included among the curves of Fig. 5. In the intermediate skin-effect range, equation 11 for the radial current density has been evaluated for a number of values of τ by the use of a digital computer. Typical values are plotted for $\tau = 0.1$ in Fig. 6. Values of steady-state radial and axial current densities are shown in Figs. 7 and 5, respectively.

Although the results given for axial current density are restricted to $r' = 0$ much useful information can be obtained; in particular, these values are applicable in the estimation of the central depth of craters to be produced by discharges.[1-3]

It is of considerable interest to determine the relationship of τ to time in seconds and the corresponding time

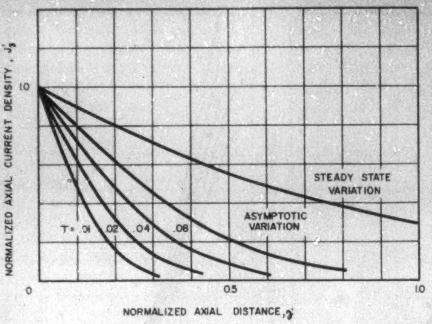

Fig. 5. Axial current densities in plane electrode as function of normalized axial distance (depth below surface of conductor) on central axis of discharge; various values of τ

boundaries for pronounced skin-effect, moderate skin-effect, or steady-state conditions. The relationship of τ to "real" time is a function of electrode permeability and conductivity, and of the discharge current and current density. Table I lists some values of real time corresponding to values of τ for two current densities and two electrode materials. The first value of current density, 10,000 amp (amperes) per square inch, is of the order of magnitude of current densities in sustained arcs in gases at atmospheric pressure; in such arcs current density is constant with time. The second, very high, value of current density is typical[2,3] of initial transient values following sparkover in a liquid dielectric. Here progressively growing cross-sectional areas and, correspondingly, progressively decreasing current densities are always involved so that the values of τ listed are useful only in estimating the extent of skin-effect. However, as a means of arriving at a quick decision as to skin-effect, or no skin-effect, the data are useful.

For example, there is considerable interest at present in the development of electric spark machine tools for the forming of large aircraft dies, involving working gaps of the order of several square feet or more in cross sections. Pulse currents of the order of 10,000 amps with durations of not more than 50 μsec (microseconds) have been suggested as design objectives although these currents are considerably in excess of those that have been used in the past and, indeed, in excess of currents for which there is any operating experience. It is clear from Table I that for such discharge currents and with electrodes of good conductors, or especially of ferromagnetic tool steels, there will be well-defined skin-effect in the electrode surfaces and, consequently, that the amounts of material removed will be less than those anticipated on the basis of earlier experience with smaller currents.

It is also of particular interest to examine the computed current densities for the ferromagnetic alloy and the nonferromagnetic alloy of otherwise similar mechanical properties in the experiment described by Williams and Smith[3] to show the influence of current density beneath an electrode surface on the depth of the craters formed by high current-density discharges. The mechanism of formation of craters in the short-duration discharge has been a very controversial subject. Widely advanced theories[6] attribute the crater formation entirely to heat transfer from the discharge. It seems clear, however, that in such a case current distribution beneath the anode surface would have no effect unless, indeed, there should be an additional thermal contribution from i^2R losses in the electrode. The latter, however, can be shown to be very small. The field-force theory, however, attributes crater formation primarily to axial current density, at least for short-duration high current-density discharges. In order for a difference in depth to appear as a result of difference in skin-effect it is necessary that the removal of material from an electrode shall take place during the time interval in which skin-effect is important. The discharge current, current duration, and electrode material parameters in the experiment cited were such that τ approaches the value of unity in an elapsed time of the order of 0.1 μsec. This suggests, there-

fore, that an appreciable amount of crater formation must have taken place in a time interval shorter than 0.1 μsec. This conclusion and the general character of experimental data reported by Williams[3] and Smith suggest that crater formation takes place continuously and progressively during a discharge. Although this is not a very surprising deduction it is nevertheless at variance with the physical process suggested elsewhere.[9]

Nomenclature

All physical quantities are given in rationalized mks units.

J = axial current density at surface of conductor
I = total current flowing out of conductor
$A=\pi r_0^2$, the area of current source
r_0 = radius of the area of current source
$\mathbf{E}$ = electric field intensity
$\mathbf{H}$ = magnetic field intensity
$\mathbf{B}$ = magnetic flux density
ρ = charge density per unit of volume
ϵ = electric permittivity of conductor
μ = magnetic permeability of conductor
σ = electric conductivity of conductor
t = time
r, ϕ, z = radial, angular, and axial co-ordinates respectively in cylindrical co-ordinate system
$\mathbf{J}$ = electric current density $=\sigma\mathbf{E}$
J_r, J_z = radial and axial components, respectively, of the current density
J_r', $J_z'=J_r/J$, J_z/J = normalized radial and axial current density respectively
$r'=r/r_0$ = normalized radial distance
$z'=z/r_0$ = normalized axial distance
$\tau=t/\mu\sigma r_0^2$ = normalized time parameter
J_{rss}', J_{zss}' = normalized steady-state radial and axial current density respectively

Appendix

Referring to Fig. 2, the axial current density of the source is

$$J=\frac{I}{A} \tag{1}$$

in which

I = total current flowing out of the conductor
$A=\pi r_0^2$, the cross-sectional area of the discharge

Maxwell's equations govern the electric and magnetic field variation in the conductor.

These are

$$\nabla\times\mathbf{E}=-\frac{\gamma\mathbf{B}}{\gamma t} \tag{2}$$

$$\nabla\times\mathbf{H}=\sigma\mathbf{E}+\epsilon\frac{\gamma\mathbf{E}}{\gamma t} \tag{3}$$

$$\nabla\cdot\mathbf{E}=\frac{\rho}{\epsilon} \tag{4}$$

$$\nabla\cdot\mathbf{B}=0 \tag{5}$$

Since the source is circular a cylindrical coordinate system is used. Let r, ϕ, and z represent the radial, angular, and axial coordinates respectively.

The boundary conditions for this physical situation are

$$\begin{aligned} J_z\Big|_{z=0} &= J,\ 0\leq r<r_0\\ &=0,\ r_0<r\leq\infty \end{aligned}$$

$$J_z=J_r=0,\qquad \sqrt{z^2+r^2}=\infty$$

The initial conditions are

$$J_z=J_r=0,\ t<0$$

$$J_z=J,\ \underset{\substack{z=0\\ t\geq0}}{0\leq r<r_0}$$

The net charge densities in the conductor are assumed to be negligible. For this case the charge density term, ρ/ϵ, in equation 4 as well as the displacement current density, $\epsilon\partial\mathbf{E}/\partial t$, in equation 3 may be neglected for this analysis because times are to be considered which are long relative to the relaxation time, ϵ/σ, of the conductor. ϵ/σ is of the order of 10^{-14} μsec for a good conductor. Under these assumptions equations 2 through 4 can easily be shown to reduce to two equations in terms of the current density.

$$\nabla^2J_z=\mu\sigma\frac{\partial J_z}{\partial t} \tag{6}$$

$$\nabla\cdot\mathbf{J}=0 \tag{7}$$

in which

∇^2 = Laplacian operator in cylindrical coordinates
$\nabla\cdot$ = divergence operator in cylindrical coordinates

Equations 6 and 7, together with the boundary conditions and initial conditions required for J_z, are sufficient for solutions for J_z and J_r. First, to solve for J_z, the Laplace transform of equation 6 is taken. The boundary conditions imposed on J_z are also transformed. The inverse Laplace transform of the resulting solution in the s domain yields a solution for J_z in the time domain. This solution for J_z is used to obtain the solution for J_r through equation 7.

The Laplace transform of equation 6 yields

$$\nabla^2J_z(s)=\mu\sigma sJ_z(s) \tag{8}$$

in which

$J_z(s)=\mathcal{L}[J_z(t)]$

The combination of boundary and initial conditions for J_z are

$$J_z\Big|_{z=0}=f(r)=\frac{J}{s},\ \underset{z=0}{0\leq r<r_0}$$

$$J_z=0,\quad \sqrt{z^2+r^2}=\infty$$

Solution of equation 8, subject to the boundary conditions, can be shown to yield

$$J_z=\frac{J_{r_0}}{s}\int_0^\infty J_1(k_{r_0})J_0(kr)e^{-\sqrt{k^2+\mu\sigma s}\,z}\,dk \tag{9}$$

in which

$J_0(u)$ = the Bessel function of first kind, order zero, with argument u
$J_1(u)$ = the Bessel function of first kind, order one, with argument u

The inverse Laplace transform of the solution in the s domain, represented by equation 9, can also be shown to yield

$$J_z' = \int_0^\infty J_1(k)J_0(kr')\cdot\frac{1}{2}\{\epsilon^{-kz'}\times [1+\mathrm{Erf}(y)]+\epsilon^{kz'}[1-\mathrm{Erf}(x)]\}\,dk \qquad (10)$$

in which

J_z', r', z', and τ = meanings given in the Nomenclature.
$x = z'/2\sqrt{\tau}+k\sqrt{\tau}$
$y = -z'/2\sqrt{\tau}+k\sqrt{\tau}$
$\mathrm{Erf}(u)$ = the error function with argument u

A solution for J_r can be effected through the use of equation 7. Solution of this equation can be shown to yield

$$J_r' = \int_0^\infty J_1(k)J_1(kr')\cdot\frac{1}{2}[\epsilon^{-kz'}\{1+\mathrm{Erf}(y)\}+ \epsilon^{kz'}\{1-\mathrm{Erf}(x)\}]dk + \frac{\epsilon^{-z'^2/4\tau}}{\sqrt{\pi\tau}}\int_0^\infty J_1(k)J_1(kr')\,\frac{\epsilon^{-k^2\tau}}{k}\,dk \qquad (11)$$

Equations 10 and 11 reduce in the steady state to

$$J_{z_{ss}}' = \int_0^\infty J_1(k)J_0(kr')\epsilon^{-kz'}dk \qquad (12)$$

$$J_{r_{ss}}' = \int_0^\infty J_1(k)J_1(kr')\epsilon^{-kz'}dk \qquad (13)$$

These steady-state solutions check with those given for an analogous problem in hydrodynamics.[7,8]

An asymptotic form for radial current density may be derived for small values of τ and values of r' sufficiently removed from $r'=1$. This can be shown to be

$$J_r' \approx \frac{\epsilon^{-z'^2/4\tau}}{\sqrt{\pi\tau}}\cdot\frac{r'}{2},\ r'<1 \qquad (14A)$$

and

$$J_r' \approx \frac{\epsilon^{-z'^2/4\tau}}{\sqrt{\pi\tau}}\cdot\frac{1}{2r'},\ r'>1 \qquad (14B)$$

The asymptotic form for J_r' can be substituted in equation 7 to obtain an asymptotic form for J_z' as

$$J_z' \approx \mathrm{Cerf}\left(\frac{z'}{2\sqrt{\tau}}\right),\ r'<1 \qquad (15A)$$

and

$$J_z' \approx 0,\ r'>1 \qquad (15B)$$

in which

$\mathrm{Cerf}(u)$ = the complementary error function with argument u

Evaluation of the axial current density has not been carried out in its entirety because of the complexity of numerical work involved. However, a comparison of the asymptotic form and the steady-state solution should permit an estimate of axial current density at intermediate values of τ. The steady-state axial current density at $r'=0$ is

$$\underset{r'=0}{J_{z_{ss}}'} = \int_0^\infty J_1(k)\epsilon^{-kz'}dk = 1-\frac{z'}{\sqrt{1+z'^2}} \qquad (16)$$

This function appears with the asymptotic curves of Fig. 5.

Engineering Aspects of TASI

K. BULLINGTON
NONMEMBER AIEE

J. M. FRASER
NONMEMBER AIEE

FOR MANY YEARS telephone people have been intrigued with the idea of making use of the idle time during a telephone call. Time Assignment Speech Interpolation (TASI) is a high-speed transmission and switching system based on the principle of using the free channel time to interpolate additional talkers. Although TASI requires considerable terminal equipment, it can approximately double the usefulness of long expensive channels such as the deep sea submarine cable systems. The first speech interpolation system is expected to be placed in service during 1960 on the first transatlantic telephone cable system between London and New York, which was opened for service in September 1956.

The basic principles of TASI are old. An extensive investigation of the feasibility of speech interpolation systems was conducted in 1946 and 1947 by A. C. Dickieson, P. G. Edwards, and others. An experimental model was demonstrated in 1950 by A. E. Melhose, and this was later extended and improved by R. L. Carbrey.

In a normal 2-way conversation each talker ordinarily uses the circuit for only about half of the time. In addition, the circuit may not be used momentarily while the operator is trying to get the right people together, or while an individual comes to the phone or takes the normal pauses between sentences and even syllables. All of these gaps add up to a substantial amount of free time. Measurements on working circuits shown in Fig. 1 indicate that the average activity (percentage of time that energy above a very low threshold is transmitted in one direction) is no more than 35 to 40% of the time that the circuit is busy at the switchboard. Since long-distance circuits use separate pairs of wires or separate carrier channels for the two directions of transmission, it follows that, on the average, each 1-way channel is free for 60 to 65% of the time.

An attempt to interpolate two or more independent conversations on a single channel would create considerable delay and mutual interference, since the probability of two talkers wanting the same channel at the same time is moderately high. However, when 2 or 3 dozen channels are operated as a group, these variations in individual activity tend to average out and the probabilities can be counted on to minimize the mutual interference to a point where there will be no noticeable effect on continuity of conversation. For example, even when all the channels are busy, at least one channel on the average is available for reassignment every L/c seconds where L is the average talkspurt length (which is somewhat less than one second)

Paper **59-70**, recommended by the AIEE Wire Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted October 31, 1958; made available for printing November 28, 1958.

K. Bullington and J. M. Fraser are with the Bell Telephone Laboratories, Inc., Murray Hill N. J.

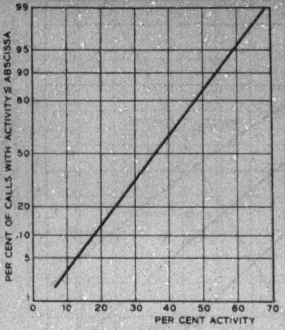

Fig. 1. Measured activity distribution on transatlantic calls

and c is the number of channels in the group.

A simplified block diagram for a TASI system is illustrated in Fig. 2 for one direction of transmission. An identical but independent arrangement is used for the opposite direction. Each of the n lines from the toll switchboard is equipped with a speech detector which is capable of recognizing the weakest speech within 5 milliseconds or less. When the speech detector on line 1 operates, the TASI switching network connects line 1 to an idle channel, say channel c, and then sends on that channel, a 10 to 15-millisecond coded signal which instructs the distant receiving terminal to connect that channel to listener line 1. Once a connection has been set up it is maintained until someone else needs a channel, even though the person may stop talking in the meantime. A similar 10- to 15-millisecond coded signal is used for disconnect purposes, but this is sent over a separate channel reserved for this purpose in order to avoid interference to the listener.

When speech appears on any of the n lines, the speech must be recognized by the speech detector, which causes some clipping during the first few milliseconds. This type of clipping can be minimized by increasing the sensitivity of the speech detector. The sensitivity cannot be too high or it will operate too often on noise, which is undesirable because it increases the activity and hence reduces the TASI advantage. A compromise is needed to achieve minimum activity while maintaining satisfactory speech quality for even the weak talkers.

The potential impairment caused by the loss of speech energy below the sensitivity of the speech detector, and by the time delay required to set up a connection, can be made negligible by design. Another possible impairment is inherent in any line-concentration arrangement but it can be minimized to any desired degree by limiting the number of lines to be served. This factor is the possibility that the number of individuals who are talking or starting to talk at a particular instant will exceed the number of available channels. For example, telephone subscribers on a party line must share time with their neighbors on a single pair of wires leading to the central office. In addition, all trunk lines between two or more central offices may occasionally be busy and a call coming in at that instant will experience some delay. In a similar manner, TASI may occasionally be overloaded by an unusually large number of simultaneous talkers. In this case, however, the information cannot be delayed and any failure to make an almost instantaneous connection results in a loss of speech transmission, called a freezeout, until a channel becomes available. It appears that the effect on transmission quality is negligible as long as the percentage of lost speech, freezeout fraction, is less than 0.5%.

During periods of light traffic the system operates essentially the same as without TASI and hence there can be no TASI impairment. However, as the load increases, the amount of switching and possible impairment increases. The objective is to limit the number of busy lines to a point where the resulting impairment is not noticeable to the average listener and is not objectionable to the more critical listener.

The number of circuits that can be made available for service at the toll switchboard, for a freezeout fraction of 0.5%, is greater than the number of physical channels by the TASI multiplying factor shown in Fig. 3. As the number of channels in the group increases, the number of potential conversations approaches a limit set by the reciprocal of the average activity. It will be noted that a 36-channel group, such as is available in present submarine cable systems, achieves a substantial TASI advantage, but that the application of TASI to only 12 channels or less is much less attractive. For an average activity in the range of 35 to 40%, it appears that the use of TASI on a 36-channel group can at least double the number of available circuits and still maintain good quality.

The average number of simultaneous talkers, np, is the product of the number of busy lines, n, multiplied by the average activity p. When the average number of simultaneous talkers is approximately equal to the number of channels c, there is a 50% chance that a new talker will be frozen out momentarily. This does not mean that 50% of the speech is lost, but there is noticeable impairment. In order to allow for variations around the average and to achieve satisfactory quality, the average number of simultaneous talkers, np, should be limited to a value that will satisfy the approximate condition of $np+\sqrt{np}\leq c$. This approximate expression is based on a more exact derivation given in the Appendix. When

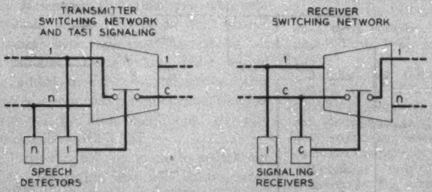

Fig. 2 (above). TASI block schematic

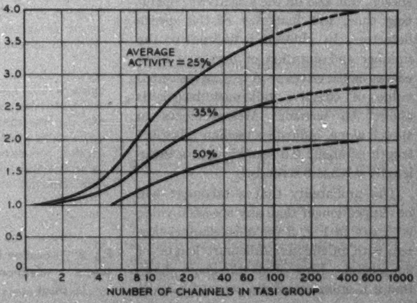

Fig. 3 (right). TASI advantage for a freezeout fraction of 0.5%

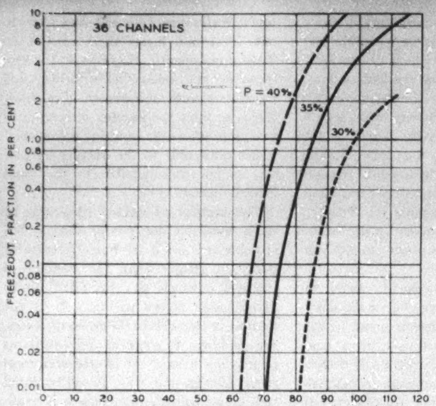

Fig. 4. Freezeout fraction versus activity and number of busy lines

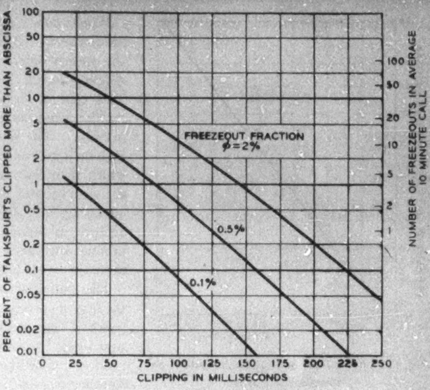

Fig. 5. Magnitude of clipping

this criterion is met, only a small percentage of the connections will experience any degree of freezeout except that required for the connect signaling code.

The expected freezeout fraction is shown in Fig. 4 as a function of the number of busy lines working on 36 physical channels for a talker activity of 30 to 40%. Listening tests have shown that a freezeout fraction of 0.1% is barely perceptible to a critical listener. A value of 0.5% is noticeable to the critical listener but is ordinarily not apparent to an average listener who is intent on understanding a message. A value of 2% would be somewhat objectionable, and a value of 5 to 10% would be definitely objectionable.

The average length of freezeout is roughly proportional to L/c, where L is the average talkspurt length and c is the number of channels. The average talkspurt length for TASI purposes depends not only on the characteristics of speech, but also on the sensitivity, operating time, and hangover of the speech detector. In addition, it depends on the number and duration of bursts of noise echoes on the circuit. A typical measured value of effective talkspurt length is about 0.6 seconds. Measurements of speech alone, indicate a median talkspurt length of about 0.6 seconds and a mean length of 1.5–1.8 seconds.[1]

The probability that a talkspurt will be clipped longer than any specified value is shown in Fig. 5 for a 36-channel system with an effective talkspurt length of 0.6 second. First of all, the chart shows that a 15-millisecond clip occurs for TASI signaling each time a new connection is needed. During the busy hour, this may occur on almost every talkspurt, but the number of operations will be reduced considerably in nonbusy hours. The three lines sloping toward the right represent three different freezeout fractions. For example, the middle curve labeled 0.5% indicates 0.5% of the talking time has been lost because a channel was not available. In this case, about 6% of the talkspurts are frozen out more than the 15-millisecond signaling time and 1% of the talkspurts are frozen out for 80 milliseconds or longer. A freezeout longer than 80 milliseconds can be expected about 4 times during an average 10-minute call. For comparison purposes, it is worth noting that the average syllable length is about 125 to 250 milliseconds. On the average, less than one talkspurt in 10,000 will be frozen out for as long as 1/4 second, and this will occur only once in about 30 calls during the busy hour.

As mentioned earlier, a talker holds a channel until his speech detector indicates that he has finished talking and until someone else needs a channel. This is true on all but three of the available channels. One channel is reserved full time for disconnect and other control purposes, and two talking channels taken at random are disconnected when possible in order to have a channel instantly available for the next talker.

Switching from channel to channel during a conversation also causes some variations in circuit noise and net loss. It is expected that a little noise will be introduced in the receiving circuits in order to prevent a completely dead receiver during the silent intervals. The variations in net loss are not expected to

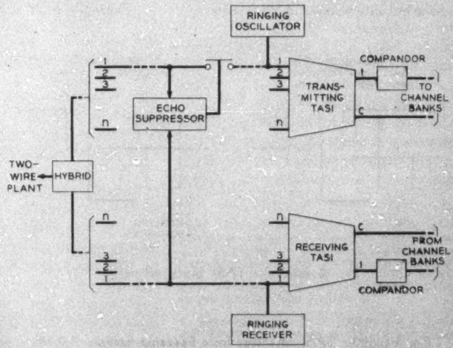

Fig. 6. Location in 4-wire telephone plant

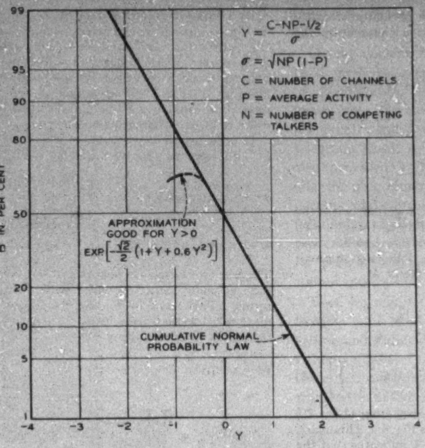

Fig. 7. Probability of freezeout $B_{(c,n,p)}$

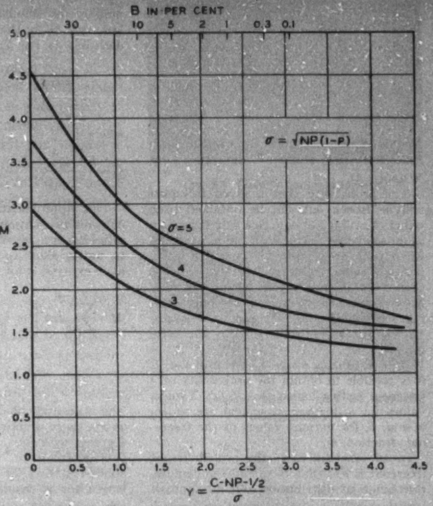

Fig. 8. Factor used in determining average length of freezeout

be important as long as the plant is maintained to meet the present objectives.

TASI is designed to take advantage of the characteristics of 2-way conversational speech. It requires a channel width of about 3,000 cycles in order to accommodate the tones needed for the rapid connect and disconnect signaling.

Telegraph or data systems that use frequency shift or frequency modulation will lock up the TASI speech detector 100% of the time and hence be transmitted satisfactorily. On the other hand, the use of on-off telegraph or data systems will require either a means for locking the speech detector or a separate channel outside the TASI complement. The high activity of telegraph and data systems requires an essentially full-time channel and hence reduces the number of conversations that TASI can yield

TASI will be located in the 4-wire part of the telephone plant, as shown in Fig. 6. It requires that split-type echo suppressors be used to insure that echoes cannot seize an outgoing circuit at either end. Compandors, which are to be added to deep sea submarine cable systems on a channel-by-channel basis as required by noise conditions, are also compatible with TASI.

Provision will be made to switch out TASI for testing purposes. In order not to affect service, circuits will be removed as they become idle until the number of circuits available to the switchboard is no greater than the number of physical channels before TASI is removed.

Because TASI is a time-sharing device, there are problems involved in transmitting supervisory and dialing pulses over TASI. TASI can work satisfactorily with the present ringdown manual basis but it is obvious that continuous supervision by means of a steady tone during the idle time cannot be used. Likewise, dial pulses cannot compete for a TASI channel on the same basis as a talker because TASI clipping would cause signaling errors. Various schemes using spurt signaling are being investigated for use when dialing over TASI is required.

Appendix

The TASI principle has been recognized for many years, and several individuals, including R. I. Wilkinson, have contributed to the mathematical analysis of speech interpolation. The following summary is based on a more complete analysis given in an unpublished 1953 memorandum by H. Cravis.

Assume that there are n independent talkers, each of whom has an average activity p competing with an individual test call (total number of talkers $= n+1$). At any particular instant, the probability that the number of simultaneous talkers will equal or exceed c (where c is less than n) is given by the cumulative binomial distribution, $B_{(c,n,p)}$.

$$B_{(c,n,p)} = \sum_{x=c}^{n} \frac{n!}{x!(n-x)!} p^x (1-p)^{n-x} \qquad (1)$$

The probability of a freezeout lasting longer than t seconds is given by $B_{(c,n,\theta)}$ where $\theta = pe^{-t/L}$ for an exponential talkspurt distribution, or $\theta = p(1-t/L)$ for a constant talkspurt length. The assumption of an exponential distribution of talkspurt lengths is the best simple approximation to the experimental data. The use of a constant talkspurt length does not change the over-all result significantly. In this expression L is the average talkspurt length.

It can be shown that the average freezeout length for an exponential talkspurt distribution is

$$t_F = L \sum_{k=c}^{n} \frac{1}{k} \frac{B_{(k,n,p)}}{B_{(c,n,p)}} \qquad (2)$$

$$= \frac{L}{c} M \qquad (3)$$

$$\text{where } M = \left[1 + \frac{c}{c+1} \frac{B_{(c+1,n,p)}}{B_{(c,n,p)}} + \frac{c}{c+2} \frac{B_{(c+2,n,p)}}{B_{(c,n,p)}} + \ldots \right] \qquad (4)$$

This series converges rapidly so only a a few terms are needed for sufficiently accurate results.

The fraction of the speech that is frozen out is

$$\Phi = \frac{t_F B_{(c,n,p)}}{L} = \frac{M}{c} B_{(c,n,p)} = \sum_{k=c}^{n} \frac{1}{k} B_{(k,n,p)} \qquad (5)$$

Tables of the binomial distribution are available for accurate computations. However, in the range of interest to TASI, this function is almost identical with the cumulative normal probability law, that is,

$$B_{(c,n,p)} \approx \frac{1}{\sqrt{2\pi}} \int_{u=y}^{\infty} exp\left[\frac{-u^2}{2}\right] du \qquad (6)$$

where

$$y = \frac{c - np - 1/2}{\sqrt{np(1-p)}}$$

In this expression the mean value is $np + 1/2$ and the standard deviation $\sigma = \sqrt{np(1-p)}$.

The probability that a given talkspurt will be frozen out can be obtained from either equation 1 or equation 6 and is shown as a solid line on Fig. 7. For example, when $y = 1$, 16% of the talkspurts will experience some degree of freezeout because there are more talkers than channels. Most of these freezeouts will last only a few milliseconds so the percentage of speech that is lost is less than 16% by the ratio t_P/L.

By substituting $\theta = pe^{-t/L}$ for p in Fig. 7, it is possible to obtain the probability of a freezeout lasting longer than t/L. Typical values for a 36-channel system are shown in Fig. 5, for various values of the freezeout fraction Φ.

In all practical cases the probability of freezeout is less than 50% and the cumulative binomial distribution and its approximation, the cumulative normal-probability law, can be further approximated by the dash line on Fig. 7, that is,

$$B_{(k,n,p)} \approx exp\left[-\frac{\sqrt{2}}{2}(1 + y_k + 0.6 y_k^2)\right] \quad \text{for } B < 0.5 \qquad (7)$$

where

$$y_k = \frac{k - np - 1/2}{\sigma} = y_c + \frac{k - c}{\sigma}$$

This approximation, together with the omission in equation 4 of the factors $c/(c+1)$, $c/(c+2)$, etc., which are less than but close to unity, leads to the following approximate expression for the factor M

$$M \approx \sum_{k=c}^{\infty} exp\left[-\frac{\sqrt{2}}{2}\frac{k-c}{\sigma} \times \left(1 + 1.2 y_c + 0.6\frac{k-c}{\sigma}\right)\right] \qquad (8)$$

The magnitude of M varies from about 1.5 to 3 or more as shown in Fig. 8. This chart, together with equation 3, indicates that the average freezeout, when it occurs, is only about 1/10 to 1/20 of the average talkspurt length in a 36-channel system.

By the use of equation 5 and Figs. 7 and 8, Fig. 4 can be constructed and similar charts for other values of c can be obtained. A cross plot of such data for a constant value of Φ yields curves of TASI advantage like Fig. 3. The TASI advantage is $n + 1/c$ since there must be $n + 1$ potential talkers in order to have n competing talkers.

In order to achieve a value of Φ less than 1%, it is necessary for $y > 1$, that is,

$$y = \frac{c - np - 1/2}{\sqrt{np(1-p)}} > 1$$

or $c > np + \sqrt{np} - \sqrt{np}(1 - \sqrt{1-p}) + 1/2$

The last two terms are opposite in sign and each is small compared with the first two terms. This leads to the simple approximate relation that a practical TASI should be limited to the following condition:

$$np + \sqrt{np} < c$$

A Transistorized 20-Channel Carrier Telegraph Terminal

T. M. GRYBOWSKI
NONMEMBER AIEE

W. G. VIETH
MEMBER AIEE

SINCE ITS INTRODUCTION in 1938 the FM (frequency-modulated) carrier has found ever-increasing use in the Western Union Telegraph Company. The gradual evolution from the type-*15* to the current type-*40* carrier telegraph terminal has shown an increase from two telegraph channels per bay, to 10 channels in the same space. The equipment herein described mounts two 10-channel groups per bay along with associated power supplies, bias and leg controls, and metering and monitoring facilities. This design has been designated as the type-*60* channel terminal.

Physical Description

The design of the type-*60* channel terminal decided upon in the planning phase of the project included consideration of the degree of size reduction made possible in a completely transistorized equipment, the practicability of manufacture, and the ease of installation and maintenance. These considerations resulted in the complete equipment being mounted on what is now known as channel terminal bay *601-A*.

The *601-A* bay consists of a standard 19-inch equipment rack upon which the equipment is mounted and occupies 9 feet 4 inches of vertical rack space. The components of the equipment are mounted in order from top to bottom as shown in Fig. 1. At the top are the terminal blocks where the external carrier and d-c signal circuits are terminated and where the various components on the bay are interconnected. Next is the carrier coupler panel, not visible in Fig. 1, that contains four line-isolating transformers, one for each direction of transmission for two channel groups. The power distribution panel contains d-c power-indicator-type fuses that distribute leg and transistor battery to the individual channels. This location, near the top of the bay, provides good visibility of the blown fuse indicator lamps without occupying more useful operating space. The power is brought to this panel from the potential cabinet at the bottom of the bay by a flexible conduit in the space between the rack channels.

Distribution of positive and negative 125-volt leg battery and negative 25-volt transistor battery to each channel takes place through the wiring duct shown at the left side of the rack. Below this panel are five rack shelves, each mounting two of the 10 channels of channel group 1. Beneath channel group 1 and located at a convenient height are grouped the metering, monitoring, and control facilities for all channels on the bay. The 10 channels of group 2 and a potential cabinet and power entrance box complete the bay. The potential cabinet contains the leg battery and transistor battery rectifiers, the main fuses, power switch, and a utility outlet. The power entrance box provides termination for external 115-volt a-c power, and circuit and frame grounds.

A single type-*60* channel terminal consists of a plug-in transceiver *650-A* and

associated tuned networks as shown in Figs. 2 and 3, and remotely located leg current and receiving bias controls. The transceiver plugs into its supporting shelf, illustrated in Fig. 4, and is secured by means of a camlock fitted with a shaft which terminates on the front panel in a 2-position OPEN and LOCK knob. The networks plug into the transceiver chassis and are fastened in place by screws. Each transceiver contains electronic sending and receiving circuits which are identical for all channels. The operating frequency of the transceiver is determined by the particular tuned networks associated with it.

Circuit considerations led to the use of a receiving polar relay type *202-A* which mounts in a socket on the transceiver face. To meet the wide variety of d-c circuit conditions encountered in the telegraph plant, a "stunt box" socket is also provided. The stunt box or leg adaptor plug illustrated in Figs. 2 and 3 permits make-break leg operation on a full-duplex, half-duplex, or duplex repeater basis. Other plugs are available for polar, telex, and a wide variety of special applications.

Each leg adaptor plug is secured by a locking latch that can be released by raising and sliding its handle to the right. Other controls on the transceiver face include a transmitter ON–OFF switch, a transmitter LEVEL control, and a number of test-pin jacks. Only sufficient test points are provided to determine if the unit is defective so it may be replaced immediately with a spare unit to maintain service. Fig. 5 shows a rear view of the transceiver with the networks removed and the hinged side panels open to expose the transistorized subpanels.

The control facilities for the bay shown in Fig. 1 consist of a jack panel and control panel for each channel group, and a common meter panel. The jack panel permits the meter panel to be corded into the sending and receiving leg circuits of any particular channel so that testing and regulating functions may be performed. The control panels contain a sending and receiving leg rheostat and a receiving bias control for each channel. Practically all of the heat dissipation in the bay is concentrated in the leg rheostats.

Fig. 2. Channel terminal type 60

Fig. 3. Channel terminal type 60, partially disassembled

This was a major consideration in the rack layout to avoid exposure of transistor circuitry to excessive temperatures. This resulted in an open framework mounting for the rheostats and a louvered front cover to provide maximum ventilation.

The back of the rack shelves visible in Fig. 4 are also perforated for ventilation of the battery tap resistors mounted on the rear of the transceiver chassis. The perforated and louvered covers on the potential cabinet and control panels, in conjunction with the space between the rack channels, create a chimney effect causing air flow through the bay. This prevents excessive temperature rise. Measurements indicate a maximum rise within any transceiver of only 12 C

(degrees centigrade) above ambient room temperature.

The *601-A* bay represents a marked change in design of carrier equipment and methods of mounting. Panels and mounting shelves are now essentially a part of the rack, and the plug-in shelf-mounting concept for the transceivers and plug-in power supplies make for ease of shipment, installation, inspection, maintenance, or replacement. The bay design permits assembly of the permanently mounted components and complete wiring of the bay to be performed at the factory. At installation it is only required to set the bay in place, wire the external transmission facilities to the terminal blocks at the top of the bay, and a-c power and grounds to the power distribution box. The transceivers and power supplies are then plugged in place to complete the installation. The plug-in components comprise 340 pounds of the 650-pound total installed weight. The *601-A* bay required 60% less office space and 65% less power per channel than currently used equipment.

Circuit Description

The type-60 channel terminal is fully compatible with the types 20, 30, and 40 currently in use throughout the telegraph plant. In each type-60 channel terminal the marking and spacing signals frequency-modulate an audio-frequency carrier which is then combined with other channel frequencies for transmission over a carrier subband facility. The operating speed of these circuits is 75 bauds to provide suitable margin for teleprinters operating at 100 words per minute. Frequency modulation of the transmitted carrier is accomplished by lowering the carrier frequency 35 cycles below channel mid-frequency for a marking pulse, and by raising the frequency 35 cycles above mid-frequency for a spacing pulse. Ten individual channels are provided, spaced at 150-cycle intervals from 375 to 1,725 cycles per second. Both channel groups 1 and 2 of bay *601-A* utilize the same frequency allocations.

The basic block diagram of a carrier channel as arranged for make-break leg operation is shown in Fig. 6. The closing and opening of the sending leg by a printer keyboard or other keying source causes the frequency of an oscillator to be shifted to the marking or spacing frequency by a capacitive reactance switched into or out of circuit by means of a diode bridge switch. The carrier signal is amplified by a buffer stage and applied through a band-pass filter to the sending bus. Continuous adjustment of the sending level is accomplished with a gain-control potentiometer coupling the oscillator and buffer amplifier. At the receiver, a suitable band-pass filter selects the desired carrier signals from the receiving bus. These signals are amplified and limited and applied to a series-tuned discriminator. The resulting d-c polar telegraph signals pass through a d-c amplifier and operate a type-*202-A* polar relay.

Transmitter Circuit

Since the general theory of FM telegraphy has been adequately covered[1,2] this paper will describe how the new terminal differs from existing vacuum tube types particularly with respect to design features necessitated by the use of transistors.

The basic circuit of the transmitter arranged for neutral leg operation is shown in Fig. 7. Functionally, the trans-

Fig. 7. Transmitter circuit

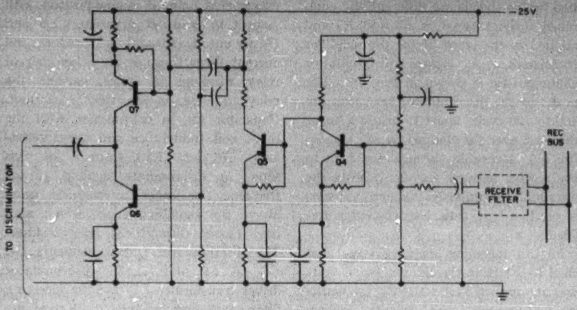

Fig. 8. Receiver limiter-amplifier

mitter consists of an oscillator, keyer, and buffer amplifier. When the sending leg is closed and the leg rheostat adjusted for a current of 70 ma (milliamperes), a potential of approximately minus 83 volts exists at point *A*. Since point *B* is held at minus 104 volts by a voltage divider, the anodes of diodes *CR*1 through *CR*4 are more negative than the cathodes by 21 volts, causing them to be nonconducting.

The oscillator frequency is determined by *L*1, *L*2, *C*1, *C*2, *C*3, and in small part by the emitter base or diffusion capacitance of transistors *Q*1 and *Q*2. When the sending leg is open, point *B* becomes positive with respect to *A*, and the diodes conduct. As a result, capacitor *C*2 is short-circuited and the resonant frequency is determined by *L*1, *L*2, *C*1, and *C*3. By design, the two resonant frequencies differ by 70 cycles. The use of the diode bridge configuration minimizes the induction of a keying transient into the oscillator tuned circuit.

The oscillator circuit is of the push-pull, common (grounded) emitter type similar in operation to the vacuum tube equivalent. The similarity is obvious if the correspondence between collector, base, and emitter of the transistor and the plate, grid, and cathode, respectively, of the vacuum tube is considered. N-p-n transistors are used because they provide greater frequency stability with temperature change than p-n-p types. This is true since the emitter-base capacitance of the typical n-p-n is less than one tenth that of the typical p-n-p. The corresponding change of capacitance due to temperature change is reduced proportionately. An output is taken from a tap on the primary of *L*1 and applied through the send level control *R*3 to the base of buffer amplifier *Q*3. Potentiometer *R*3 permits a continuous adjustment of the transmitter carrier level. A carrier level of plus 7.5 dbm (power in decibels referred to 1 milliwatt) is available at the output of the sending filter. The input impedance of the send filter is 7,500 ohms and the output impedance 600 ohms. The sending filter and the oscillator circuit components *C*1, *C*2, *C*3, *L*1, *L*2, and *R*2 are mounted in the sending network located on the left side of the transceiver and visible in Fig. 1 through 4. The network connectors are polarized to prevent the insertion of a sending network into a receiving network position or vice versa. A sending network is identified by the letter designation of the channel on the handle as well as by a type number and channel frequency stenciled on the top of the network container, visible in Fig. 3. The hole in the handle allows access to trimmer *C*3, which provides frequency adjustment.

RECEIVER CIRCUIT

The receiver circuit is diagrammed in Figs. 8 and 9. The received carrier signal passed by the receiving filter enters the limiter-amplifier, consisting of transistors *Q*4 through *Q*7, see Fig. 8. Here amplitude variations in the incoming signal are removed and the signal is raised to the constant level required to drive the discriminator. The discrimi-

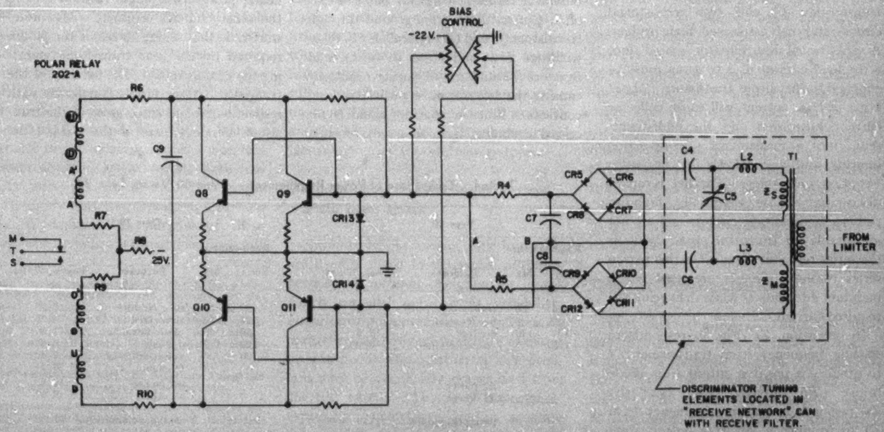

Fig. 9. Receiver discriminator and d-c amplifier circuits

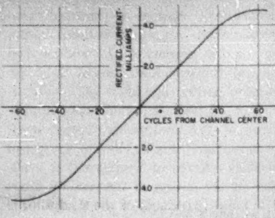

Fig. 10. Typical discriminator characteristic

nator driver transistors, $Q6$ and $Q7$, are connected in a complementary symmetry arrangement to provide uniform loading of the discriminator transformer $T1$ and also to simplify the circuit. For signal levels of less than −45 dbm, $Q4$ acts essentially as a class A amplifier. For larger signals limiting begins. Transistor $Q5$, directly coupled to $Q4$, further amplifies and limits the signals. For inputs in excess of −55 dbm the gain of $Q4$ and $Q5$ is sufficient to saturate the output transistors, resulting in an 18-volt peak-to-peak square wave at primary of $T1$.

The discriminator converts the incoming FM carrier to d-c polar signals. These signals are in turn amplified by transistors $Q8$ through $Q11$ to operate a polar relay. Four transistors are used as a protective measure since, under the 3-fold circumstance of loss of incoming carrier, an ambient temperature of 55 C, and proper or improper setting of the receiver bias control, the dissipation ratings of the transistors can be exceeded.

The discriminator consists of driver transformer $T1$ and two series-tuned circuits and their associated diode bridges. A series-tuned discriminator is used since a d-c load current of 3 to 4 ma must be supplied to the output transistors. About 1 ma of base current will cause collector current saturation and the added current gives a measure of post-detection limiting and also allows for transistor variation and aging. Parallel resonant discriminators are essentially high-impedance high-voltage circuits and are not as suitable for transistor applications as the series resonant type. For this reason series resonant circuits are used which maintain adequate Q while delivering the required current.

In operation, Zs (Fig. 9) responds to spacing frequency from transformer $T1$ to produce a positive output from diode bridge $CR5$ through $CR8$. Similarly, Zm responds to marking frequency from $T1$ to produce a negative output from diode bridge $CR9$ through $CR12$. The two bridge signals are differentially combined through resistors $R4$ and $R5$ and applied to the input of the d-c amplifier transistors. A typical discriminator characteristic is shown in Fig. 10. The peaks in the discriminator responses are 100 to 120 cycles apart to insure a linear response over the channel band. Capacitor $C5$, accessible through the hole in the receive network handle, adjusts the discriminator tuning so that zero response is produced at the channel center frequency.

For an incoming marking signal applied to $T1$ from the limiter, equal voltages are applied to Zm and Zs, the marking and spacing tank circuits, respectively. Zm, tuned close to the marking frequency, provides a low impedance to the induced voltage; Zs, tuned away from the marking frequency, presents a high impedance. As a result, more current flows through the marking bridge, $CR9$ through $CR12$, than through the spacing bridge, $CR5$ through $CR8$. Capacitors $C7$ and $C8$ act to filter the rectified output of the diode bridges and remove the harmonics of the detected carrier frequency. Because a larger voltage is developed across $C8$, point A becomes negative with respect to point B. Current flows from point B through diode $CR14$ and the emitter-base circuits of transistors $Q8$ and $Q9$ to cause these transistors to conduct. The voltage drop across diode $CR14$ biases the bases of transistors $Q10$ and $Q11$ to cutoff.

A negative voltage on the base of a p-n-p transistor results in conduction; conversely a positive potential at the base will result in collector current cutoff.[3] Current flows from ground through transistors $Q8$ and $Q9$ in parallel, $R6$, relay windings U-D and A'-A in series, and resistors $R7$ and $R8$ to negative battery causing the relay to close on its marking contacts. When a spacing signal is received a similar train of events occurs, except that point A is now positive with respect to point B, transistors $Q8$ and $Q9$ are cutoff, $Q10$ and $Q11$ conduct, and current flows through the other pair of relay windings in series, causing the relay to close on the spacing contact. Capacitor $C9$, in conjunction with the relay coil inductance and series resistances $R6$ and $R10$, form a low-pass filter to discriminate against carrier frequency or other interference lying above the signalling range which may have passed through the receiver filter. The discriminator tuning elements $C4$, $C5$, $C6$, $L2$, and $L3$, the discriminator driver transformer $T1$, and the receiving filter are mounted in the plug-in receiving network located on the right side of the transceiver as shown in Figs. 1 through 4. The receiving network is distinguishable in that it mounts a designation clip and omits the channel letter designation on the handle. As with the sending network, the network type number and channel frequency are also stenciled on the top of the container.

Power Consumption

The extent of miniaturization and reduction in power consumption achieved with this equipment was possible only through the use of transistors. Their low-voltage low-current requirements, without the need for filament-supply voltage, caused a significant reduction in power consumption. Each transceiver, containing 11 transistors, requires only 1.25 watts of power for its operation (25 volts at 50 ma) exclusive of telegraph leg power. This is less than the heater power for a single vacuum tube in the older channel terminal. Also noteworthy is that about 30 ma of the 50 are required by the four transistors operating the output relay. The polarity of the transistor battery supply is negative with respect to ground since most of the transistors employed are of the p-n-p type.

Table I. Comparison of Power Requirements: Type 60 Versus Type 30

Type 60				Type 30			
Requirement				Requirement			
Volts	Ma	Purpose	Power, Watts	Volts	Ma	Purpose	Power, Watts
−25	50	transistors	1.25	+120	18	tube circuits	2.16
−22	5	bias control	0.11	−120	73	tube circuits	8.76
−125	140	d-c legs	17.5	50	20	bias control	1.0
−125	7	voltage divider	0.875	−120	140	d-c legs	16.8
				−120	20	voltage divider	2.4
						filament	26.2*
		leg power	17.5			leg power	16.8
		all other	3.8			all other	40.5
		total per channel	21.3			total per channel	57.3

* 25 volts a-c, 1.05 amperes.

A comparison of the power requirements of the type *60* and the type *30* is shown in Table I. Of interest is the fact that a bay of 20 type-*60* channels requires less total power than one of 8 type-30 and occupies no greater floor space.

MAINTENANCE

In order to reduce the need for and facilitate maintenance where required, a certain design philosophy has been followed. These ideas may be grouped generally under three headings: quality components, use of test points and other failure indicating devices, and plug-in construction. The quality components employed include hermetically sealed paper and solid electrolyte tantalum electrolytic capacitors for coupling and bypass purposes in the transistor circuits. Silvered mica and Mylar film capacitors are used in the tuned circuits of the sending and receiving filters, oscillator, and discriminator tanks. Ferrite cup-core inductors are used in the oscillator and discriminator tuned circuits. Industrial or computer quality transistors are used to insure long life. Silicon junction rectifiers are employed in the power supplies.

Test points, visible in Figs. 1 and 2, on the front of the channel transceiver, facilitate testing and aid in localizing faults. The indicator fuses located on the power distribution panel and the potential cabinet signal the failure of a particular channel or power supply. Primary power and leg circuit fuse indicators are of the neon glow lamp type. Transistor and bias circuit fuse indicators are of the incandescent lamp variety.

Conclusion

The design objectives of this development have been substantially achieved. The advantages of space saving, flexibility and self containment as to power supply and test facilities, and reduced heat dissipation, enhance the value of this equipment. Both small offices where load requirements make but a single voice-frequency band necessary or large installations where space problems, floor loading, and air-conditioning load are becoming serious are likely locations for the use of this equipment. The use of reliable and long-lived components should considerably reduce the cost of maintenance.

Tests Conducted Over Highly Reflective Terrain at 4,000, 6,000, and 11,000 Megacycles

A. OXEHUFWUD
NONMEMBER AIEE

DURING the past 10 years the American Telephone and Telegraph Company has conducted tests at 4,000 mc (megacycles) over most major microwave radio relay routes prior to the initial installations. As the necessity for further expansion arises, it is planned to add 6,000-mc and, possibly, 11,000-mc circuits to the existing routes. For this reason antenna height versus path loss tests were performed over four paths with highly reflective terrain in Colorado and Wyoming. The purpose of these tests was to collect information to permit the evaluation of performance at the higher frequencies on existing paths from the results of earlier 4,000-mc tests when a common antenna is used for all frequencies. To obtain comparable results simultaneous measurements were made at 3,950 and 6,310 as well as 3,950 and 11,200 mc. The 3,950-mc measurements were used for reference purposes.

Purpose of Antenna Height Versus Path Loss Tests

Antenna height versus path loss tests are usually made to determine optimum permanent antenna heights for paths which require high circuit reliability. Locations and elevations of obstructions and reflecting surfaces which are of major importance in the solution of this problem may be accurately determined from the test results. This is of importance, especially when there are no accurate topographic maps available. When only one reflecting surface exists in a path, the problem is usually a simple matter. More frequently, however, there are multiple surfaces. The reflections from each surface may not be severe but, if even numbered Fresnel zone reflections from two or more of these surfaces should happen to coincide, cancellation of the desired signal can be intolerable. Therefore it is very important that the location and elevation of each reflecting surface be known and, also, the severity of the reflections. When this has been established through antenna height versus path loss tests, it is usually possible to select antenna heights which will prevent coinciding reflections regardless of changes in bending of the rays caused by variations in atmospheric refraction. In 1950 and 1955, 4,000-mc tests were made over the paths which are to be discussed in this paper. Thus the major obstructions and reflecting surfaces were already known. It is interesting to note that the tests made in July and August of 1950 and those made in April and early May of 1957, checked almost exactly, reading for reading.

Types of Test Equipment

The test equipment employed to measure the path loss at 3,950 mc consisted of a Western Electric Company, Inc., type *TE-2* transmitter and receiver. The 6,000-mc equipment was RCA (Radio Corporation of America) *TVM-1A*, and the 11,000-mc equipment Lambda-Pacific Engineering, Inc., *1200K*.

Paper 59-86, recommended by the AIEE Radio Communication Systems and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted October 14, 1958; made available for printing December 11, 1958.

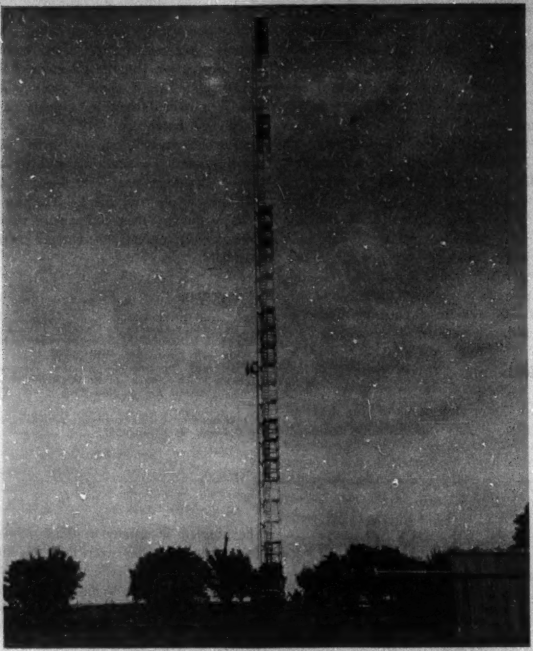

Fig. 1. 200-foot portable tower

With the 4,000-mc equipment 57-inch parabolic antennas were used. The 6,000- and 11,000-mc. equipments were equipped with 48-inch parabolic antennas. Vertical polarization was used with the 4,000-mc, horizontal with the 11,000-mc and both were tried with the 6,000-mc tests. To obtain the expected level at the receiver input for free space transmission the transmitter output is measured and added to the gains of the two antennas. This sum is then subtracted from the computed free space loss between two isotropic antennas for the path length between the transmitter and the receiver. A test signal is then applied to the receiver input at the free space level just mentioned. An attenuator inserted ahead of the main intermediate-frequency amplifier is adjusted to give a standard reading on a meter which measures the rectified output from the amplifier. The attenuator setting is recorded and used as a reference. Similarly, during the tests the attenuator setting required to give the standard reading on the meter for the received signal is recorded and, using the reference setting, the actual path loss is calculated. Portable towers 200 feet in height were equipped with tracks and two carriages mounted on these tracks, each holding one radio-frequency equipment with its associated antenna. The carriages were mounted in tandem one above the other and spaced about 5 feet between the center line of the antennas.

Fig. 1 shows a 200-foot portable tower. Fig. 2 shows the vehicle housing the receiver control units and the calibration equipment. The radio-frequency unit with the antenna is hoisted up and down the tower by means of a hand winch, which is equipped with an indicator giving the height of the center line of the antenna above ground. Fig. 3 shows the method for mounting the 4,000-mc equipment on the carriage below the 6,000-mc RCA equipment. During the 11,000-mc tests the Lambda Pacific equipment replaced the RCA unit.

Testing Methods

Antenna height versus path loss tests consist of path loss measurements at various antenna height combinations. For instance, the antennas at the transmitter and the receiver are both raised simultaneously in equal steps, or one antenna is held fixed at a certain height while the other is moved. Usually moving an antenna in 5-foot steps and measuring the path loss is satisfactory but, if the terrain is highly reflective, even a few inches at a time can be too much to notice the effect of every reflection. As the frequency is increased, the spacings between the Fresnel zone effects on the desired signal become smaller necessitating that the antennas be moved cautiously in very small steps. To analyze the test results a curve is plotted showing the path loss versus the antenna heights.

Because of irregularities in the carriage tracks and backlash in the antenna mountings it is always necessary to orient the antennas both vertically and horizontally for maximum received signal after they have been moved to a new position. This is done by remotely controlled motors. When no significant reflections are encountered or when the angle between the direct and reflected signals is small, this procedure is satisfactory. On the other hand, with a highly reflective surface near one end of a path with an elevation considerably lower than at the distant end, the problem becomes more involved. The angle between the direct and the reflected signals may then be so large that the directivity of a high-gain antenna partially differentiates between the two signals. Then the maximum or minimum signal is not received when the antenna at the end nearest to the reflecting surface is oriented in the direction of the direct signal path.

This may best be explained by the following example in which the angle between the direct and the reflected rays is large and the antennas are set at such heights that the path of the reflected signal is an odd multiple of one-half wavelength longer than the direct path (an odd-numbered Fresnel zone). If the vertical angle of the antenna nearest to the reflecting surface is changed from one extreme to the other, the received signal will increase gradually and go through a maximum, when the combined effect of the direct and reflected rays is the greatest. This will occur when the antenna is pointed below the direction from which the direct ray is arriving. On the other hand, should the antennas be set at such heights that the path of the reflected signal is a multiple of one wavelength longer than the direct path (an even-numbered Fresnel zone), the received signal will behave differently. If the antenna nearest to the reflecting surface is

Pt. 1
1959

Fig. 2 (above). Vehicle housing receiver control units

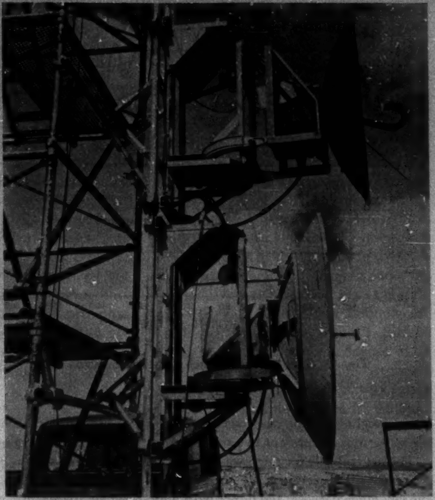

Fig. 3 (right). Mounting arrangement for 6,000-mc equipment (top) and 4,000-mc equipment (bottom)

pointed several degrees up from the horizontal and then is slowly oriented downward, the cancellation effect between the signals will vary as follows. As the antenna is oriented more toward the direct beam, the signal increases until a maximum is obtained. This occurs before the antenna is pointed in line with the path of the direct beam because the reflected signal is beginning to interfere. Thereafter, the received signal decreases and a minimum is obtained when maximum cancellation occurs between the two signals. As the antenna is pointed further downward, the signal again reaches a maximum when the reflected signal is stronger than the direct signal because of the antenna discrimination pattern. This will occur when the antenna points in a direction which is lower than the path of the reflected beam. During tests over this type of terrain, special attention is paid to this problem as it can be of importance in determining the proper orientation of the permanent antennas, especially when a common antenna is used for several frequency bands.

Paths Tested

Tests using 6,310 and 11,200 mc were made over four paths. Two of them were selected for the great difference in elevation between the sites and also for the smooth reflecting surfaces near the low end of each path. These were Buckhorn Mountain to Greeley in Colorado, and Rawlins to Creston in Wyoming. The other two paths, Bitter Creek to Creston, and Evanston to Church Butte, both in Wyoming, were chosen because they contained well-defined multiple reflecting surfaces more toward the center of the paths, so that the angle between the direct and reflected paths was small with respect to the beam widths of the antennas.

The characteristics of these paths and the antenna heights during the tests are as follows:

Buckhorn Mountain to Greeley:

Path length.............. 44.1 miles
Elevation at Buckhorn Mountain..............8,300.0 feet
Elevation at Greeley.......4,860.0 feet
Transmitter antenna at Buckhorn Mountain fixed at................ 52.5 feet

Receiver antenna at Greeley varied. Reflecting surfaces consisting of bare cultivated fields located within 4 miles of Greeley site

Rawlins to Creston:

Path length.............. 27.7 miles
Elevation at Rawlins......7,712.0 feet
Elevation at Creston......7,182.0 feet
Transmitter antenna at Rawlins fixed at........ 17.0 feet

Receiver antenna at Creston varied. Reflecting surfaces consisting of grass-covered desert located within 5 miles of Creston site.

Bitter Creek to Creston:

Path length.............. 39.3 miles
Elevation at Bitter Creek..7,096.0 feet
Elevation at Creston......7,182.0 feet

Transmitter antenna at Bitter Creek and receiver antenna at Creston both varied. Reflecting surfaces consisting of grass-covered desert located immediately in front of Bitter Creek and 6 to 7 miles from Creston

Evanston to Church Butte:

Path length.............. 36.8 miles
Elevation at Evanston....7,686.0 feet
Elevation at Church Butte.7,055.0 feet

Transmitter antenna at Evanston and receiver antenna at Church Butte both varied. Reflecting surfaces consisting of grass-covered desert and sparse sage brush close to both sites and 12.5 miles from Evanston.

Results of Tests

The tests confirm that the 6,000- and 11,000-mc transmissions follow the same pattern as the 4,000-mc transmission; thus, the analysis of the test results can be made in the normal manner. The parameter *k* being the ratio of the effective earth curvature to the true earth curvature is generally accepted as a means of expressing the amount of bending of a ray caused by atmospheric refraction. At 4,000 mc during daytime hours and uniform weather conditions, *k* seldom deviates appreciably from 4/3. However, if possible, the value of *k* should be determined at the time of each test to permit the proper analysis of the test results. Even though the tests discussed in this paper were not conclusive because of the lack of obstructions toward the center of the path, where a change in bending is the greatest, the indications are that there is a very slight decrease in *k* when the frequency is increased. However, as the change is so small, the same value of *k* can for all practical purposes be used with these frequencies when determining an-

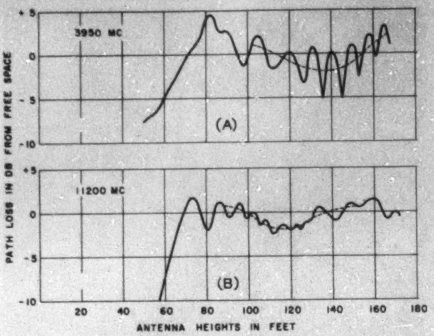

Fig. 4. Tests between Church Butte and Evanston

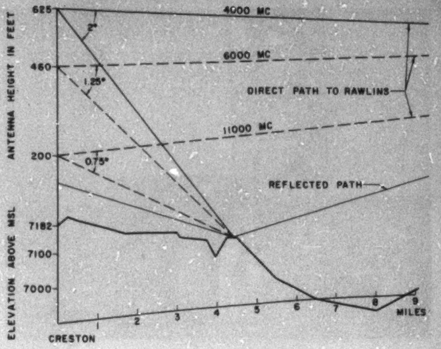

Fig. 5. Profile near Creston

tenna heights, except when severe multiple reflections are present in a path.

The general rule for microwave paths is that when no reflections are present and the clearance between the direct path and the highest obstruction is 0.6 or more of the first Fresnel zone radius, a signal close to the computed free space signal is received. The Fresnel zone radius is a function of frequency. When the frequency is increased, the radius becomes smaller, and thus less path clearance is required. An antenna fixed at the height needed for 4,000-mc transmission will therefore be satisfactory at 6,000 and 11,000 mc as the clearance will be greater than required.

When the frequency is increased, the gain of the antenna is also increased. This results in a narrower beam width, which gives greater discrimination against undesirable nearby reflections. This is evidenced in the test results by a decrease in amplitude of peaks and dips caused by the odd and even Fresnel zone effects. Fig. 4(A) shows the result of a 3,950-mc test between Church Butte and Evanston. Fig. 4(B) is an identical test made simultaneously at 11,200 mc. The long, sweeping valley which occurs at about 140 feet in Fig. 4 (A) and 117 feet in (B) is caused by an even Fresnel zone reflection from a surface 12.5 miles from Evanston. Thus the angle between the direct and reflected paths is small and there is no antenna discrimination at either frequency. The maximum reduction in signal is about the same: 2 db (decibels) below free space. The closely spaced peaks and dips are caused by reflections from surfaces near both ends of the path. At 4,000 mc, Fig. 4(A), the difference between the maxima and minima reaches as high as 6 db, whereas at 11,000 mc, (B), it is only about 2 db on account of the greater antenna discrimination.

In paths with reflections the advantage of greater antenna discrimination at the higher frequencies can best be illustrated by the following example. In the Creston to Rawlins path the location of one major reflecting surface is about 4.5 miles from Creston and its ground elevation is 100 feet lower than at this site. With vertical polarization the vertical beam width of a Western Electric Company horn reflector antenna is 2.0 degrees at 3,740 mc, 1.25 degrees at 6,325 mc, and 0.75 degrees at 10,960 mc.

To obtain half-power discrimination against reflections from the aforementioned surface, a 625-foot tower would be required at Creston to obtain an angle of 2.0 degrees between the direct and the reflected rays with a frequency of about 4,000 mc. At 6,000 mc a 460-foot tower would suffice to give an angle of 1.25 degrees, and at 11,000 mc a 200-foot tower will give 0.75 degree. This is shown in Fig. 5.

The fact that the antenna discrimination increases with frequency tends to give an impression that any path suitable for 4,000-mc transmission can also be used for the higher frequencies from the point of view of reflections. For several reasons this is an erroneous impression; as a matter of fact, any path showing evidence of severe reflections must for many reasons be carefully studied before its suitability can be determined for the frequencies in question. For instance, often the 4,000-mc antennas are mounted low behind a ridge so that the latter will block undesirable reflections from nearby surfaces beyond the ridge, and also so that the clearance between the direct path and the ridge remains within the limits of the first Fresnel zone for any value of k between 2/3 and infinity. This is done in order to prevent undesirable coinciding even-zone reflections from reaching the receiving antenna. At the Creston site, for instance, the towers were erected in a gully as shown in Fig. 6. The antennas facing Rawlins were located at such a height, 31 feet, that the clearance between the direct path and the ridge during normal transmission conditions is about equal to the radius of the first Fresnel zone. This is illustrated with a dashed line in Fig. 7(A) which shows a height-loss curve taken at 3,950 mc. The tests were made when $k=4/3$. The total apparent change in earth curvature is only ±3.25 feet at the ridge, when the value of k drops to 2/3 or rises to infinity. Thus, it is evident that the received signal will not drop below free space. Fig. 7(B) shows the results of an identical test made at 6,310 mc. Apparently the same antenna height can be used at Creston.

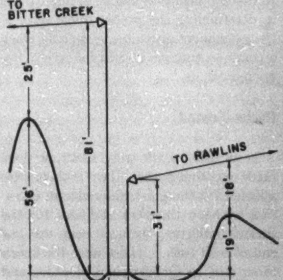

Fig. 6. Antenna arrangement at Creston

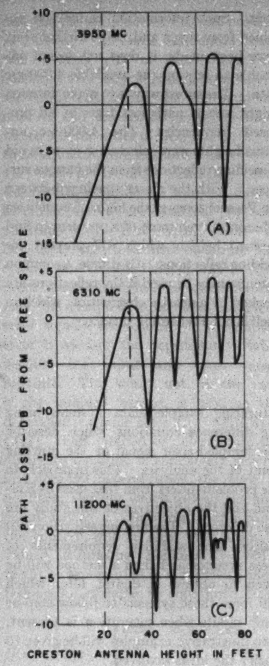

Fig. 7. Tests between Creston and Rawlins

The results of the 11,200-mc tests are shown in Fig. 7(C). If a common antenna is used, the received signal will even under normal transmission conditions be influenced by the second Fresnel zone reflection. During an increase in k, the loss will be even greater, especially at times when the ground is covered by snow or ice. If the antenna is lowered to 28 feet above ground to accommodate the 11,000-mc band, it may not affect the 4,000- and 6,000-mc transmissions severely, but the clearance above the ridge is reduced to such an extent that any vehicle passing on the road which runs along the ridge will cause a loss in signal. Furthermore, the physical dimensions of the horn reflector antenna prevent such a low antenna height. A solution to the problem is to locate separate 11,000-mc antennas at an elevation of 200 feet or more. At this height the angle between the direct and the reflected paths will exceed the antenna discrimination angle sufficiently to prevent severe signal cancellations.

Possible variations in reflection coefficient with frequency could not be determined from these tests in the absence of accurate information with respect to the performance characteristics of the test antennas at the higher frequencies. Tests using 6,310 mc were conducted between Buckhorn Mountain and Greeley using both horizontal and vertical polarization. There was no noticeable difference in the results. The peaks and dips in signal strength caused by the ground reflections were of the same magnitude, indicating that the phase angle and the reflection coefficient from the bare fields were the same for both types of polarization. This, however, may not be true in other terrain and under other circumstances. The effect of precipitation at the higher frequencies could not be studied as the weather conditions remained favorable throughout the tests.

Conclusions

The purpose of these tests was to collect certain information which will permit determining from earlier 4,000-mc tests the feasibility of using a common antenna for 4,000-, 6,000-, and 11,000-mc transmissions over existing paths. The conclusions drawn from the tests are as follows.

In paths which show no evidence of undesirable reflections there appear to be no other restrictions for using a common antenna than possibly the path length. Some existing 4,000-mc paths being up to 50 miles long may prohibit the use of 11,000 mc as a result of additional attenuation caused by precipitation.

Paths with only one reflecting surface will require a study of the 4,000-mc tests to determine if they are suitable for 6,000 and 11,000 mc. If the reflections are severe, the 4,000-mc antennas are preferably placed at such heights that the clearance between the direct radio path and the surface reamins greater than 0.5 but never more than 1.25 of the first Fresnel zone radius, as k varies from 2/3 to infinity. Because of the smaller Fresnel zone radii at 6,000 and 11,000 mc, the first zones will not occur at the same antenna heights and therefore the antennas must be placed at lower heights to avoid signal cancellation due to second-zone reflections. Furthermore, if the reflecting surface is located toward the center of the path, where the effect of atmospheric refraction is the greatest, the radio paths for the higher frequencies will not remain within these limits as k varies, even if separate antennas are used at different heights.

In paths with a reflecting surface close to one end the temptation is to orient vertically for the maximum signal. Regardless of frequency this will result in a very poor signal when a change in atmospheric refraction places a beam in an even zone above the reflecting surface, causing maximum cancellation in signal. When a common antenna is used, the higher frequencies will be even more vulnerable to misorientation, since the beam width becomes narrower. This can be illustrated by the following examples. Assume that the reflection coefficient is unity; the angle between the direct and reflected paths at the antenna nearest the reflecting surface is 2 degrees; and the antennas are oriented for maximum received signal. In the first example the heights of the antennas are such that the direct beam is under the influence of an odd Fresnel zone reflection. At 4,000 mc the received signal will have a broad peak with a maximum when the antenna is pointed one degree below the direct path. At 11,000 mc the signal will suffer a considerable loss, since the half-power beam width is only 0.75 degree and the antenna is oriented one degree away from either the direct or the reflected paths. In the next example it is assumed that the antennas are set at such heights that the direct beam is under the influence of an even Fresnel zone reflection. If they are oriented for the upper maximum, the antenna nearest the reflecting surface will be pointing above the direct path. Again the 11,000-mc signal will suffer some loss but it will not be as severe as in the previous example, since the angle to the direct path will be considerably smaller than one degree and at this frequency the antenna will discriminate against the reflected signals. No doubt, discrimination against undesirable reflected signals can be obtained by vertical orientation of an antenna and this seems to point toward a solution to the problem, but exaggerated misorientation of an antenna may severely reduce its ability to discriminate against signals polarized 90 degrees with respect to each other.

A common antenna may be used for paths where the existing antenna heights are such that the reflecting surface is affectively blocked by nonreflecting obstructions, or where the angle between the direct and reflected paths is so large that the antenna discriminates against the reflections. If these conditions are not fulfilled it may require separate antennas for satisfactory transmission. Paths over smooth earth such as water and salt flats are special cases which have so far, been tested with 4,000 mc only. Probably the reflections will affect the 6,000- and 11,000-mc transmissions in a similar manner, so the proper antenna heights can be calculated from the existing 4,000-mc data. Nevertheless it seems advisable to conduct some tests to obtain further knowledge about matters pertaining to this type of terrain and the effect of, for instance, salt storms on the path attenuation. Often the antenna at one end of a path is located several hundred feet higher than the one at the low end, which is only a few feet above ground, to keep the direct radio path within the limits of the first Fresnel zone. In such cases it may become physically impossible to mount a 6,000- or 11,000-mc antenna low enough.

Paths with multiple reflecting surfaces present a more complicated problem. The loss to the direct signal contributed by even Fresnel zone reflections from each surface separately may not be severe, but if the antenna heights are not properly selected the reflections from two or more surfaces will no doubt coincide during some bending condition. The combined effect can be severe enough to make the circuit unreliable. To predict without testing how the 6,000- and 11,000-mc transmissions will behave at present antenna heights is very difficult, if not impossible. It is necessary to have a complete and accurate knowledge of the paths with respect to the location and elevation of all reflecting surfaces, as well as obstructions. Such information cannot be obtained from maps and, until further tests have been made, it does not seeem advisable to rely on the available 4,000-mc data. The surest way is to make antenna height versus path loss tests at all proposed frequencies. The 4,000-mc antenna heights were selected so as to avoid coinciding reflections from the various surfaces. With the closer spacings between the Fresnel zones at the higher frequencies it becomes even more of a problem to find antenna heights which will prevent coinciding reflections. Of course, a common antenna may be used if the reflections are blocked by a nearby obstruction, which in itself is not a reflecting surface.

The Stability and Compensation of Saturating Sampled-Data Systems

FRANCIS J. MULLIN
ASSOCIATE MEMBER AIEE

Synopsis: Sampled-data feedback systems which contain a saturating element are investigated in this paper. A condition which must be satisfied if these systems are to be stable is developed; it is shown that this is a necessary condition for stability and an intuitive argument is presented to indicate that this condition is probably sufficient. Finally, a method to obtain a digital filter for compensating and/or stabilizing these systems is presented.

THE SYSTEM to be investigated in this paper is shown in Fig. 1. In particular it is wished to determine the effect of the saturating element on the response of the system when a step function is applied to the input.

Saturating sampled-data systems have been investigated previously by Nease[1] and Kalman.[2] In his study Nease considered pulse-width modulators in which the duration of the pulse applied to the system at the *n*th sampling instant was related to the error signal at the *n*th sampling instant. Since the pulse width can be no larger (in time) than the sampling period, a saturation effect between the pulse width and the sampled-error signal was necessarily introduced in his analysis. Kalman, on the other hand, discussed saturating systems in which the pulse width of sampled-error signal was small compared to the time constants of the system in which case the pulse could be accurately replaced by an impulse. This same assumption is made when the *z*-transform[3,4] or modified *z*-transform[5] are used to analyze linear sampled-data systems. Kalman was not primarily concerned with the analysis of these systems but rather with the problems involved in controlling such systems in some optimum fashion. Consequently, he talked about these systems in rather general terms and presented some concepts which can be used in finding this controlling function.

In this paper the study will be these saturating sampled-data systems using the difference equations which describe the sampled-error signal as the starting point of the analysis. This approach to the problem differs from that used by Kalman and the objectives of this study are also different. The first investigation will concern the stability requirements of these systems and then a method will be given to obtain a digital filter which will force these systems to follow step or ramp inputs when saturation is present. Two illustrative examples will be given to clarify the ideas involved.

Requirements for Stability

For this study the most convenient manner to describe the system is in terms of the sampled-error signal, $E(n)$, and its various derivatives. For notational convenience we shall use the following definitions (see Fig. 1):

$$\begin{aligned} E(n)&=e(t)\big|_{t=nT} & C(n)&=c(t)\big|_{t=nT} \\ \dot{E}(n)&=\frac{d[e(t)]}{dt}\bigg|_{t=nT} & \dot{C}(n)&=\frac{d[c(t)]}{dt}\bigg|_{t=nT} \qquad (1) \\ \ddot{E}(n)&=\frac{d^2[e(t)]}{dt^2}\bigg|_{t=nT} & \ddot{C}(n)&=\frac{d^2[c(t)]}{dt^2}\bigg|_{t=nT} \\ &\cdots & &\cdots \end{aligned}$$

$$R(n)=r(t)\big|_{t=nT}$$

T is the sampling period of the system and *n*, the independent variable of the difference equations, numbers the sampling period.

To form the difference equations which

describe the sampled-error signal, proceed as follows. The linear differential equation relating $c(t)$ to $H(n)$, which is constant over any sampling interval, is solved for $c(t)$ during the nth sampling interval and differentiated $(p-1)$ times where p is the order of $G(s)$ in Fig. 1. If these equations are evaluated for $t=(n+1)T$, then p first-order difference equations which describe the sampled output in terms of $H(n)$ are obtained. By substituting $C(n)=R(n)-E(n)$, $\dot{C}(n)=\dot{R}(n)-\dot{E}(n)$, etc., into these equations and noting that $H(n)=f[E(n)]$, the p first-order difference equations which involve only the sampled input and sampled-error signals are formed. The sampled error is used as the dependent variable because the input and error terms separate. This would not be the case if the sampled output is used as the dependent variable since $H(n)=f[R(n)-C(n)]$. This method of determining the difference equation is completely general and does not depend upon the type of nonlinear element which follows the hold circuit in Fig. 1. However, in this paper the concern will be only with a single-valued saturating nonlinearity which might be represented in a piecewise linear fashion, for example, by equation 2.

$$H(n)=f[E(n)]=\begin{cases} KE_0; & E(n)>KE_0 \\ KE(n); & -KE_0<E(n)<KE_0 \\ -KE_0; & E(n)<-KE_0 \end{cases} \qquad (2)$$

K is the gain of the linear region of the saturating element. Assume that the linear part of the system, i.e., $G(s)$ in Fig. 1, has at least one but not more than $(p-1)$ integrators. This means that the step-function response of the linear part of the system of Fig. 1 may contain terms involving $t, t^2, t^3 \ldots t^K$, but $K<(p-1)$. Then, under these conditions, for any finite sampling period, it can be shown[6] that the magnitude of the sampled-error signal is bounded. This means that the sampled-error signal must have one of two properties: 1. it can approach a constant value, i.e., an equilibrium point in the phase space, and 2. it can approach a periodic solution in the phase space, i.e., a limit cycle.

Due to the assumption that $G(s)$ possesses at least one integrator, it is known that if the sampled-error signal approaches a constant value, this constant value is zero. Also known is the fact that if any oscillations are to occur then these oscillations must take place about the origin. Again, the reason for this is that there is at least one integrator in $G(s)$ and feedback from output to input.

The system is defined stable if, to a bounded input, there corresponds a bounded output, and the system is not capable of maintaining self-sustained oscillations. It has been indicated that the error signal (or output) is bounded and we would now like to develop a condition which must be satisfied if no limit cycle is to exist in the saturated system. For the systems investigated the difference equations which describe the sampled-error signal are:

$$E(n+1)=[f_{11}(E(n),T)]E(n)+f_{12}(T)\dot{E}(n)+f_{13}(T)\ddot{E}(n)+\ldots \qquad (3A)$$

$$\dot{E}(n+1)=[f_{21}(E(n),T)]E(n)+f_{22}(T)\dot{E}(n)+f_{23}(T)\ddot{E}(n)+\ldots \qquad (3B)$$

$$\ddot{E}(n+1)=[f_{31}(E(n),T)]E(n)+f_{32}(T)\dot{E}(n)+f_{33}(T)\ddot{E}(n)+\ldots \qquad (3C)$$

In these equations the nonlinear terms appear only as coefficients of $E(n)$ since there is an amplitude-dependent nonlinearity; the other coefficients are functions of only T, the sampling period. Also, the equations are not symmetrical, i.e., $f_{ij}(T)\neq f_{ji}(T)$. If the system is to be stable, then there exists a steady-state value of the error signal (which for systems with integrators is zero) called $E_{ss}(n)$, which can be obtained from equation 3(A) with $E(n+1)=E(n)$ and all derivative terms set equal to zero. Imagine that the system has reached this steady-state value. Then, if $E_{ss}(n)$ is to be an equilibrium point, any perturbation about $E_{ss}(n)$ must result in decaying oscillations; that is, the operating point of the system must eventually return to $E_{ss}(n)$ if this operating point is changed slightly from its steady-state value. Now, if the perturbed values of $E(n)$, $\dot{E}(n)$, etc., are denoted by $e(n)$, $\dot{e}(n)$, etc., then to a first approximation, the difference equations for the perturbed error are:[1]

$$e(n+1)=\overline{f_{11}}(T,E_{ss})e(n)+f_{12}(T)\dot{e}(n)+f_{13}(T)\ddot{e}(n)+\ldots \qquad (4A)$$

$$\dot{e}(n+1)=\overline{f_{21}}(T,E_{ss})e(n)+f_{22}(T)\dot{e}(n)+f_{23}(T)\ddot{e}(n)+\ldots \qquad (4B)$$

$$\ddot{e}(n+1)=\overline{f_{31}}(T,E_{ss})e(n)+f_{32}(T)\dot{e}(n)+f_{33}(T)\ddot{e}(n)+\ldots \qquad (4C)$$

$$\cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot$$

where

$$\overline{f_{1j}}=\frac{\partial}{\partial E(n)}[f_{1j}(E(n),T)E(n)]\Big|_{E(n)=E_{ss}} \qquad j=1,2\ldots p \qquad (5)$$

Equations 4(A–C) are p first-order difference equations which can be solved for the perturbed error, $e(n)$, in a straightforward manner.[7] If the solution for $e(n)$ shows that the perturbation decreases with increasing n, then $E_{ss}(n)$ is a stable equilibrium point. On the other hand, if the solution shows that the perturbation does not decay with increasing n, then $E_{ss}(n)$ is an unstable point and a limit cycle will exist. This is certainly a necessary condition for the existence of a limit cycle.

We would now like to indicate the plausibility of this being a sufficient condition although this cannot be proved in a rigorous fashion. In the equations for the perturbed error signal 4(A–C) the quantities $\overline{f_{1j}}(T, E_{ss})$ give the slope of the saturation curve at E_{ss}. This means that the equations for the perturbed error signal are simply the nonlinear difference equations which describe the system, linearized in the vicinity of E_{ss}. Also, the equations for the perturbed error signal are the same as those of the completely linearized system where this system is one in which the saturation effect is ignored and the saturating element is assumed to have a gain of K over an indefinite range of input magnitudes. If the actual saturation curve has its maximum slope or highest gain in the vicinity of the origin, then the equations for the perturbed error signal are linearized in the vicinity of the highest gain. Now, if the completely linearized system is stable for this maximum gain, the equations for the perturbed error signal indicate decaying oscillations since these equations are the same as those of the completely linearized system. From a stability point of view the completely linearized system is "worse" than the saturated system because there are no bounds placed on the magnitude of the error signal. Consequently, it is felt that if the system is stable when the error signal is not bounded, it should be stable when this signal is bounded. And because the equations for the perturbed error signal are the same as the equations for the completely linearized system, it is believed that the previously stated condition is also a sufficient condition for stability.

In other words, the original nonlinear system has been replaced with a linear system having a gain equal to the maximum gain of the saturating system. Then if the linear system, which places no bound on the magnitude of the various signals in this system, is stable, it seems as though the saturated system, which restricts the magnitude of the various signals, should also be stable since the equations for the completely linearized system are the same as those for the perturbed error of the saturating system. The definite exceptions to this statement are those systems which are conditionally stable, in which case a root-locus plot of the poles of the completely linearized sys-

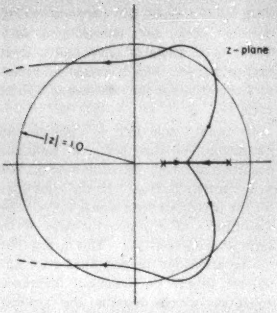

Fig. 2. A root locus plot of two poles of a conditionally stable sampled-data system. Arrows indicate the direction of increasing gain

tem is outside of the unit circle in the z-plane for certain values of gain but inside the unit circle for larger values of gain. Such a root-locus plot might be as shown in Fig. 2 and it seems likely that such a condition would occur only for very small values of T.

The summary of the stability criterion for these systems might be stated in the following manner. A necessary condition for saturating sampled-data systems which contain at least one integrator to be stable (no limit cycle exists) is that the equations for the perturbed error signal show that the perturbation decreases with increasing n. It seems plausible that this is a sufficient condition but this could not be proved rigorously.

Compensation Procedure

The system to be compensated is that of Fig. 1. It is wished to find a digital filter or discrete compensator which will operate on the sampled-error signal in such a fashion as to force the error signal to zero for inputs which are step functions of restricted magnitude or ramps with restricted slopes. In block diagram terminology this means that we want to find the $D^*(z)$ of Fig. 3 which will force the error to zero, subject to the condition that $D^*(z)$ be physically realizable. By physically realizable[8] is meant that the roots of the denominator of $D^*(z)$ must lie inside the unit circle in the z-plane and that the highest power of z in the denominator of $D^*(z)$ must be equal to, or greater than, the highest power of z in the numerator.

For simplicity, assume that what is wanted is to find a discrete compensator which will force the system to follow step functions with a restricted range of magnitudes. Apply a step function equal to the saturation level of the amplifier to the linear part of the system and find the time required for its output to reach a value equal to the maximum step function the system is to follow. This time places a lower bound on the time or number of sampling periods required for the error to go to zero for the entire range of input magnitudes and determines the minimum number of sampling periods which must elapse before the output and input can be equal for all values of the input. Now since this minimum time was determined by applying the maximum step function possible to the linear part of the system, it is obvious that the output of the system cannot be made equal to the input for all time in this minimum time. The time required to do this must be greater than this minimum time since a negative signal must be applied to the linear part of the system to keep the output from overshooting its desired value. In other words, if the system is initially driven in one direction with a series of positive pulses, then the only means of bringing the output to some constant value is to apply a series of negative pulses to the system later. If these later pulses are properly chosen it is possible to force the output to be equal to the input for all time after the second pulse sequence is applied. Thus, the initial problem which must be solved is to find a series of pulses of duration T which will cause the output and input to be the same within a reasonable length of time. The duration of these pulses must be T because the error signal of the system can change only at the sampling instants, and the magnitudes of these pulses must be less than the saturation level of the amplifier. This second condition is the one which causes the difficulty and makes this problem different from that of finding a discrete compensator for a linear system.

The series of pulses required to force the output to equal the input can be found as follows. Consider the sequence of pulses which are applied to the input of the linear element to be composed of a series of delayed step functions as shown in Fig. 4. Then, using the delayed step functions as the input to the linear part of the system, the output of the linear element can be written:

$$c(t)=\sum_{i=0}^{K} H_i h(t-iT) \tag{6}$$

where $h(t)$ is the step-function response of the linear system. The number of step functions, $(K+1)$, is determined from a consideration of the range-input magnitudes which the system should follow and it is possible to determine the range of input magnitudes for a given K. This will be pointed out in example II. This equation for $c(t)$ will contain terms which involve t and terms which do not involve t. The quantities which involve t are equated to zero for $t>KT$ and the sum of the constant terms is equated to the

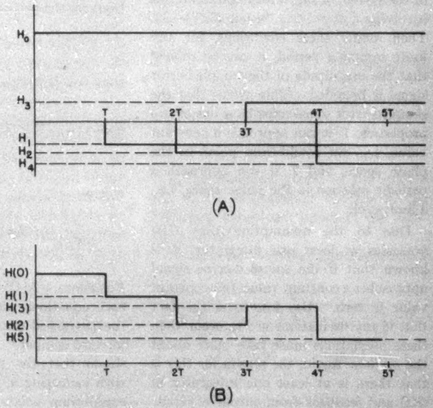

Fig. 5. The unit step-function response of $G(s)=1/s(s+1)$

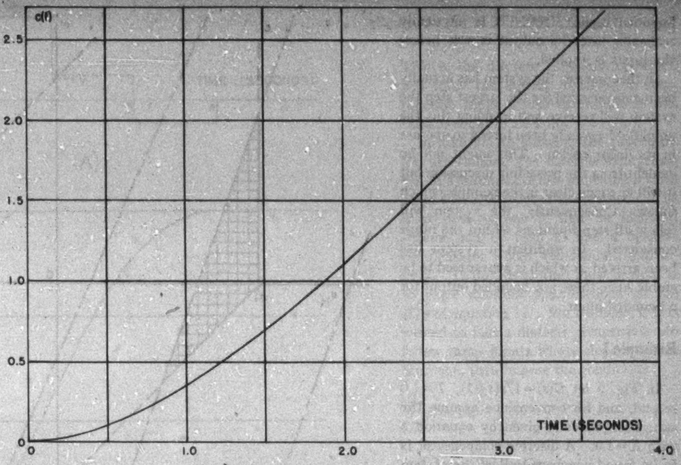

value of the largest input step function the system will receive. This gives the relationship between the H_i's necessary to force the output to be equal to the input. There will always be more unknown H_i's than there are equations indicating that some of the H_i's can be arbitrarily specified. For convenience the H_i's will be arbitrarily specified from H_0 onward. For example, if three values of H_i can be specified, then the three values chosen will be assigned to H_0, H_1, and H_2. Then solve for the unknown H_i's in terms of those specified as arbitrary.

The word arbitrary has been used loosely here since the condition of restricted magnitude must be imposed on the amplitude of the impulses. To find what must be done to satisfy this condition, let V denote the saturated output of the amplifier. Then, the restricted magnitude condition can be stated:

$$|H_0| \leqslant V \tag{7A}$$

$$|H_0+H_1| \leqslant V \tag{7B}$$

$$\cdots\cdots\cdots\cdots$$

$$|H_0+H_1+\ldots+H_K| \leqslant V \tag{7K}$$

Since all of the unspecified H_1's have been expressed in terms of those we are at liberty to specify, all of these $(K+1)$ equations can be written in terms of only those H_1's which are arbitrary. These equations take care of the magnitude restrictions and then simply find the unspecified H_1's which satisfy these magnitude conditions. After obtaining them, compute the other H_1's and obtain the desired sequence of pulses. This can be done in a straightforward manner.

Once the pulse sequence has been determined, the discrete compensator which will produce this sequence of pulses can very easily be found. Knowing the pulse sequence, the sampled output of the system and the signal $\bar{E}(n)$ of Fig. 3 may be found as also the sampled error, $E(n)$, since the sampled input and output are known. $E(n)$ is the input to $D^*(z)$ and $\bar{E}(n)$ is the output of $D^*(z)$. Both are discrete signals which are zero after a finite time. This means we can take the z-transform of these two signals and obtain

$$D^*(z)=\frac{\bar{E}^*(z)}{E^*(z)} \tag{8}$$

$D^*(z)$ will always be a stable device since it has a bounded output, $\bar{E}^*(z)$, for a

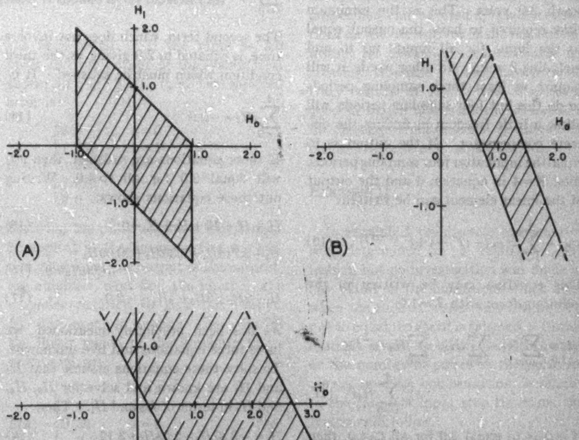

Fig. 6. (A) Magnitude restrictions imposed by equations 21 and 22. (B) Magnitude restriction imposed by equation 23. (C) Magnitude restriction imposed by equation 24

bounded input, $E^*(z)$. It is physically realizable since its output is zero before the input is applied.

In this process, the system has actually been compensated for the largest step the system will receive and in doing this the amplifier has really been forced to operate in its linear region. This might not be evident from the preceding discussion but it will be made clear in the examples which follow. Consequently, the system will follow all step functions within the range considered. In addition a system has been arrived at which is guaranteed to be stable since there is a bounded output for a bounded input.

Example I

In Fig. 3 let $G(s)=1/s(s+1)$, $T=1.0$ second, and for convenience assume the saturation curve is given by equation 2 with $K=1.0$. A discrete compensator is to be found which will allow the system to follow step inputs whose magnitudes may be as large as two units.

First find the response of $G(s)$ to the largest step function this linear network can receive. In this example it will be a unit step and for a unit step input, the output of $G(s)$ is

$$c(t)=t-1+e^{-t} \tag{9}$$

This response is shown in Fig. 5 and it is seen that it takes 2.95 seconds for $c(t)$ to reach 2.0 volts. This is the minimum time required to have the output equal to the input for all inputs up to and including 2 volts. In other words, it will require at least three sampling periods to do this but four sampling periods will allow a little freedom in finding the discrete compensator. If the output is to equal the input after four sampling periods, then $K=4$ in equation 6 and the output of the linear element can be written:

$$\underset{t\geq 4.0}{c(t)}=\sum_{i=0}^{4}H_i[(t-iT)-1+e^{-(t-iT)}] \tag{10}$$

This equation may be written in the following form with $T=1.0$

$$\underset{t\geq 4.0}{c(t)}=t\sum_{i=0}^{4}H_i-\sum_{i=0}^{4}iH_i-\sum_{i=0}^{4}H_i+e^{-t}\times\sum_{i=0}^{4}H_ie^i \tag{11}$$

If $c(t)$ is to equal 2.0 for all $t>4.0$, then the first and third terms of this equation require that

$$\sum_{i=0}^{4}H_i=0 \tag{12}$$

and the last term requires that

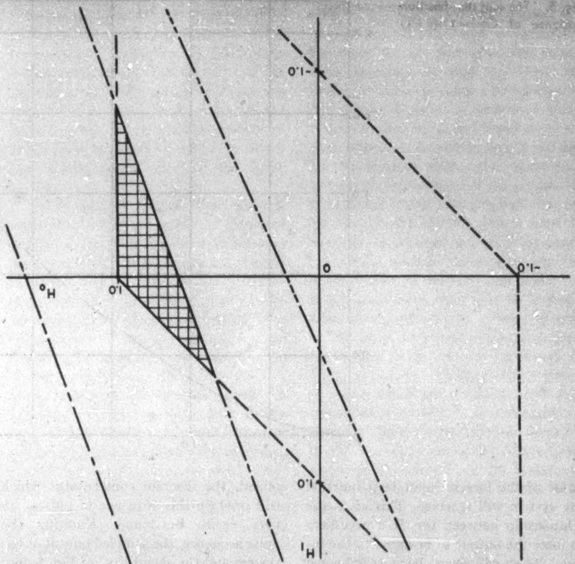

Fig. 7. The superposition of all magnitude restrictions imposed on H_0 and H_1. Shaded region shows permissible values

$$\sum_{i=0}^{4}H_ie^i=0 \tag{13}$$

The second term, which does not involve time, is equated to 2.0 giving us the third condition which must be satisfied. It is:

$$\sum_{i=0}^{4}iH_i=-2.0 \tag{14}$$

If these equations are satisfied, then $c(t)$ will equal 2.0 for all $t>4.0$. Writing out these equations shows:

$$H_0+H_1+H_2+H_3+H_4=0 \tag{15}$$

$$H_0+2.718H_1+7.39H_2+20.09H_3+54.60H_4=0 \tag{16}$$

$$H_1+2H_2+3H_3+4H_4=-2.0 \tag{17}$$

As has been previously mentioned, we have three equations and five unknowns. To solve these equations assume that H_0 and H_1 are known and solve for H_2, H_3, and H_4 in terms of H_0 and H_1. Then

$$H_2=-3.82H_0-2.03H_1+3.12 \tag{18}$$

$$H_3=3.67H_0+1.705H_1-4.25 \tag{19}$$

$$H_4=-0.86H_0-0.397H_1+1.14 \tag{20}$$

Now impose the magnitude restrictions. This is most easily done by drawing an H_0, H_1 plane and plotting the equations which must be satisfied if the magnitude of the pulses are to be limited. Refer now to Fig. 6. The first two magnitude conditions are:

$$|H_0|\leqslant 1.0 \tag{21}$$

$$|H_0+H_1|\leqslant 1.0 \tag{22}$$

Equation 21 eliminates that part of H_0, H_1 plane to the right of the line $H_0=1$ and the left of the line $H_0=-1.0$; equation 22 eliminates the section above the line $H_0+H_1=+1.0$ and below the line $H_0+H_1=-1.0$. This is shown in Fig. 6(A). The third magnitude condition is:

$$|H_0+H_1+H_2|\leqslant 1.0$$

Using equation 18 this becomes:

$$|-2.82H_0-1.03H_1+3.12|\leqslant 1.0 \tag{23}$$

Equation 23 eliminates the section to the right of the line $(-2.82\ H_0-1{,}03\ H_1+3.12=1.0)$ and to the left of the line $(-2.82\ H_0-1.03\ H_1+3.12=-1.0)$ and this restriction is shown in Fig. 6(B). The fourth condition is:

$$|H_0+H_1+H_2+H_3|\leqslant 1.0$$

And using equations 18 and 19 this becomes:

$$|0.86H_0+0.397H_1-1.14|\leqslant 1.0 \tag{24}$$

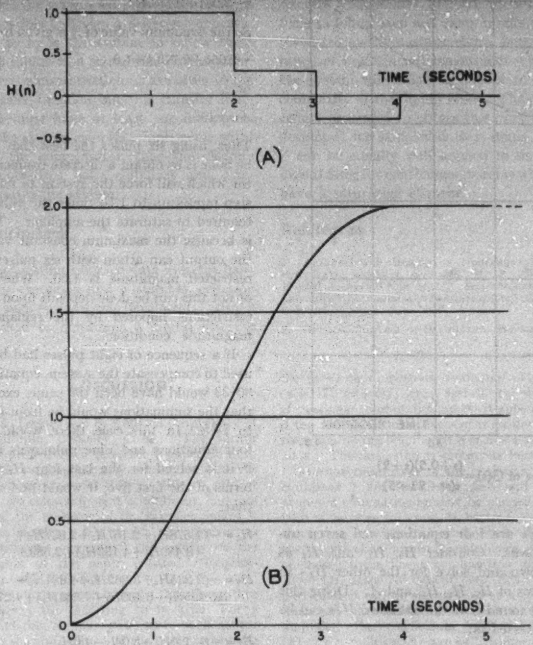

Fig. 8. (A) The pulse sequence to compensate $G(s)=1/s(s+1)$ with $T=1.0$ second. (B) The output of the system when this pulse sequence is applied to the input of $G(s)$

Equation 24 eliminates no additional region of H_0, H_1 plane as is seen in Fig. 6(C). The fifth magnitude condition is automatically satisfied since we have already imposed the condition $\Sigma H_i=0$ in determining the individual H_i's.

The result of all the magnitude restrictions is completely shown in Fig. 7. It is seen that any values of H_0 and H_1 bounded by the three lines ($H_0=1.0$), ($H_0+H_1=1.0$), and ($-2.82\ H_0-1.13\ H_1+3.12=-1.0$), will satisfy the magnitude restrictions and also force the output to equal the input in 4 seconds. To find the sequence of pulses let us arbitrarily select $H_0=1.0$ and $H_1=0$. Then $H_2=-0.70$; $H_3=-0.58$; and $H_4=0.28$. For these values of H_i, the desired pulse sequence is 1, 1, 0.30, −0.28, 0, 0, . . . This pulse sequence and the output of the linear system are shown in Fig. 8.

Since the output has been allowed to reach a value of 2.0, this is the response the system will have when the input is 2.0. Determining the discrete compensator which will give this response when the input is 2.0 units is straightforward now that the proper sequence of pulses has been found. If the input is 2.0 units and the output of the system is as shown in Fig. 8(B), then the sampled error is:

$$E(n)=\begin{cases}2.0 & n=0\\ 1.632 & n=1\\ 0.865 & n=2\\ 0.210 & n=3\\ 0.0 & n\geqslant 4\end{cases}\qquad(25)$$

Knowing the pulse sequence which must be applied to the linear part of the system, that is, at the output of the saturating amplifier, next find the input to the amplifier required to give this output. In this example assume the gain of the linear region of the amplifier to be unity and so:

$$E(n)=\begin{cases}1.0 & n=0\\ 1.0 & n=1\\ 0.30 & n=2\\ -0.28 & n=3\\ 0.0 & n\geqslant 4\end{cases}\qquad(26)$$

Using equation 8 it is finally found:

$$D^*(z)=\frac{1.0+1.0z^{-1}+0.30z^{-2}-0.28z^{-3}}{2.0+1.632z^{-1}+0.865^{-2}+0.21^{-3}}$$

or

$$D^*(z)=\frac{1.0z^3+1.0z^2+0.30z-0.28}{2.0z^3+1.632z^2+0.865z+0.21}\qquad(27)$$

This is the discrete compensator which will force the output to follow a step-function input whose magnitude is less than or equal to 2.0 units.

In addition to showing the procedure for determining the discrete compensator, this example has also indicated several other characteristics of the method. The most obvious one is that an identical scheme can be used to find a discrete compensator which will follow ramp inputs. To do this all that must be done is to place different specifications on the H_i's of equation 11. For example, if it is wished to find a discrete compensator to follow ramp inputs whose slope was less than one, then impose the conditions

$$\sum_{i=0}^{4}H_i=1.0$$

$$-\sum_{i=0}^{4}iH_i-\sum H_i=4.0$$

$$\sum H_ie^i=0$$

and find the H_i's as before, subject to the magnitude restrictions. With the H_i's determined, the discrete compensator is found exactly as it was for a step input.

Also, if the system has a time delay, this same method can be used both for step and ramp inputs. And, if it is desired, some of the H_i's which were left unspecified can be used to place restrictions on the derivatives of the response to insure, for example, a continuously increasing response. Thus, having arbitrary values of H_i at our disposal is good in that it allows additional freedom in meeting simultaneous specifications on the response and its derivatives.

Example II

In example I the discrete compensator was determined in a relatively easy fashion but no investigation was made in any detail on the limitations which arise when the time at which we wish the output to equal the input is selected. In this example it will be shown how this time, or the number of pulses in the pulse sequence used for compensation, is related to the range of input step functions the system will follow.

In Fig. 3 let $G(s)=(s+0.5)(s+2)/s(s^2+2s+s)$ and $T=1.0$ second. Also let the input-output characteristics of the amplifier be given again by equation 2 with $K=1.0$. If a unit step function is applied at the input of $G(s)$, then the output of $G(s)$ is:

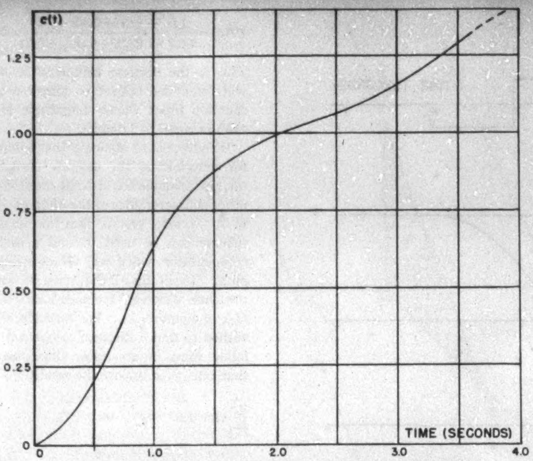

Fig. 9. The unit step-function response of $G(s)=\frac{(s+0.5)(s+2)}{s(s^2+2s+5)}$

$$c(t)=0.25+0.42-0.521e^{-t}\times \sin(2t+53.6° \text{ (degrees)}) \quad (28)$$

This response is shown in Fig. 9.

Use a sequence of six pulses to compensate the system and investigate exactly what can be done with those six pulses. With this input to $G(s)$ its output is:

$$\underset{t\geq 6.0}{c(t)}=\sum_{i=0}^{6} H_i[0.25(t-i)+0.42-0.521e^{-(t-i)}\sin[2(t-i)+53.6°]]$$

or

$$\underset{t\geq 6.0}{c(t)}=0.25t\sum_{i=0}^{6}H_i-0.25\sum_{i=0}^{6}iH_i+0.42\times\sum_{i=0}^{6}H_i-0.521e^{-t}\sum_{i=0}^{6}e^iH_i\times[\cos 2i\sin(2t+53.6°)-\sin 2i\cos(2t+53.6°)] \quad (29)$$

Now suppose that $c(t)$ = a constant, A, for $t>6.0$ and try to determine the maximum value of A. Then from equation 29 it can be seen that for this condition to be satisfied

$$\sum_{i=0}^{6}H_i=0 \quad (30)$$

$$-0.25\sum_{i=0}^{6}iH_i=A \quad (31)$$

$$\sum_{i=0}^{6}H_ie^i\cos 2i=0 \quad (32)$$

$$\sum_{i=0}^{6}H_ie^i\sin 2i=0 \quad (33)$$

Here are four equations and seven unknowns. Consider H_0, H_1, and H_2 as known and solve for the other H_i's in terms of H_0, H_1, H_2, and A. Doing this it is found that the unknown H_i's can be expressed as:

$$H_3=-1.693H_2-2.345H_1-3.051H_0+2.773A \quad (34)$$

$$H_4=-1.847H_3-2.622H_2-3.412H_1-4.216H_0+3.20A \quad (35)$$

$$H_5=2.0H_4-3.0H_3-4.0H_2-5.0H_1-6.0H_0+4.0A \quad (36)$$

$$H_6=-H_5-H_4-H_3-H_2-H_1-H_0 \quad (37)$$

In these equations specify H_0, H_1, and H_2. Then take $H_0=1.0$ to try to obtain a good initial response but let H_1 and H_2 remain arbitrary and assume that whatever these values are, they satisfy the magnitude conditions imposed by the saturation curve. This means that:

$$|1+H_1|\leqslant 1.0 \quad (38)$$

$$|1+H_1+H_2|\leqslant 1.0 \quad (39)$$

The fourth magnitude condition is:

$$|H_0+H_1+H_2+H_3|\leqslant 1.0$$

$$|-2.051-1.345H_1-0.693H_2+2.773A|\leqslant 1.0 \quad (40)$$

Now find values of H_1 and H_2 which will maximize A subject to equations 38 and 39. Since H_1 must be <0, the best choice of H_1 is $H_1=0$. Similarily if $H_1=0$, then $H_2<0$ and also is set $H_2=0$. This means:

$$|-2.051+2.773A|\leqslant 1.0 \quad (41)$$

So the maximum value of A is given by:

$$-2.051+2.773A=1.0 \quad (42)$$

or

$$A=1.10 \quad (43)$$

Thus, using six pulses the best that can be done is to obtain a discrete compensator which will force the system to follow step inputs up to 1.10 times the voltage required to saturate the amplifier. This is because the maximum constant value the output can attain with six pulses of restricted magnitude is 1.00. Whether or not this can be done depends upon the restrictions imposed by the remaining magnitude conditions.

If a sequence of eight pulses had been used to compensate the system, equations 30–33 would have been the same, except that the summations would be from $i=0$ to $i=8$. In this case there would be four equations and nine unknowns and if it is solved for the last four H_i's in terms of the first five, it would be found that:

$$H_5=-(1.578H_4+2.157H_3+2.837H_2+3.489H_1+4.133H_0)+2.583A \quad (44)$$

$$H_6=-(2.235H_5+3.262H_4+4.321H_3+5.395H_2+6.466H_1+7.534H_0)+4.275A \quad (45)$$

$$H_7=-(-2.0H_6-3.0H_5-4.0H_4-5.0H_3-6.0H_2-7.0H_1-8.0H_0)+4A \quad (46)$$

$$H_8=-(H_7+H_6+H_5+H_4+H_3+H_2+H_1+H_0) \quad (47)$$

Then, as was done with the six pulses, start finding the restrictions on the H_i's which the saturation effect causes. The maximum value of A will result if $H_0=1.0$, $H_1=H_2=H_3=H_4=0$ and then the sixth magnitude condition reduces to:

$$|H_0+H_5|=|1+H_5|\leqslant 1.0$$

or,

$$|-3.133+2.583A|\leqslant 1.0$$

This shows that the maximum value of A is given by:

$$A=\frac{4.133}{2.583}=1.60 \quad (48)$$

Thus, using an 8-pulse sequence, the best that can be done is obtain a discrete compensator which will force the system to follow step inputs up to 1.60 times the voltage at which the amplifier saturates. The remaining magnitude conditions will determine whether or not this is possible.

This example has shown how one can determine the range of input which can be followed for a given pulse sequence. This means that once the range of inputs which the system will receive is known, it is possible to design a discrete compensator to force the system to follow these step inputs in a straightforward manner. There is no restriction on the order of the transfer function but this transfer function must have at least one integrator. If the system exhibits a limit cycle without the compensator, then the discrete compensator both stabilizes and compensates the system.

Conclusions

Saturating sampled-data systems have been examined and a stability criterion for such systems was developed. Also, a method to determine a digital filter or discrete compensator to force these systems to follow step and ramp inputs was presented and it was also shown how the range of input signal magnitudes which the system will follow is related to the complexity of the digital filter. The procedure presented to obtain this filter was developed for sampled-data systems but it can be equally well applied to find a digital filter for continuous systems which have a saturating element.

◆

Discussion

C. A. Desoer and **S. Kodama** (University of California, Berkeley, Calif.): The author has presented an interesting paper on nonlinear sampled-data systems. He deserves commendation, for this is a difficult subject on two counts: first, it is nonlinear, and second, the presence of the sampler makes it time varying. We would like, however, to offer some comments* particularly on the section of the paper entitled, "Requirements for Stability."

From the paper it seems that the author believes the following to be true: For a saturating sampled-data servo such as the one shown in Fig. 1 of the paper, when the transfer function $G(s)$ is of the order p and contains at least one but not more than $(p-1)$ integrators then, for any finite sampling period, the magnitude of the sampled-error signal is bounded.

First, this theorem as it stands is misleading and may suggest incorrect conclusions, and second, a study of the author's proof (reference 6 of the paper) discloses some gaps in the reasoning.

That the theorem is misleading is best shown by a counter example:[1] Let the saturating amplifier have unity gain over its linear region and let $G(s)=1/s^2(s+1)$, then it can be shown that, if the input $r(t)$ remains equal to zero, any output phase-space trajectory which starts from the subspace defined by $c(nT)=E_0$, $\dot{c}(nT)\geq 5.5\ E_0$, $E_0\geq \ddot{c}(nT)>0$, becomes unbounded regardless of the sampling period. More precisely, it can be shown that the output behaves in an oscillatory manner; its amplitude and half-cycle period increase with time at least logarithmically.

Since the author's theorem leads to erroneous conclusions it should be useful to indicate where the proof's logic (reference 6 of the paper) is faulty. The author's method of proof consists of the following steps: 1. he *assumes* that all the derivatives of $e(t)$ of order $p-1$ and higher are bounded, 2. he uses equations 3(A), 3(B), 3(C), etc., to express $E(n+1)$ as a linear combination of the $(p-1)$th derivatives evaluated at nT, $(n+1)T$, $(n+2)T$, etc., and 3. the form of the linear combination makes it appear as if the assumed boundedness of these derivatives implies the boundedness of $E(n+1)$ for all n. This last step is erroneous because 1. in some cases some of the coefficients of equations 3 are identically zero and the proposed elimination cannot be carried out (this is the case, for example, where $G(s)$ has more than one integrator), 2. some of the coefficients of equations 3 (and, hence, some of those of the linear combination giving $E(n+1)$) actually depend on $E(n)$. In particular it can be shown that as a consequence of the saturation characteristic of the amplifier, the coefficients $f_{21}(E(n),T)$, $f_{11}(E(n),T)$. . . all go to zero as $E(n)$ becomes arbitrarily large. Since these coefficients appear in the denominator of the linear combination giving $E(n+1)$, the third step of the author's reasoning is incorrect.

In view of these considerations it should be worthwhile knowing a correct statement of sufficient conditions for boundedness of the output together with a proof that satisfies the objections just mentioned. First the statement:

For a sampled-data servo with a saturating amplifier such as that shown in Fig. 1, with the input $r(t)$ equal to zero for all $t>0$ and an arbitrary set of initial conditions (by "arbitrary set of initial conditions" is meant any set of initial conditions that can be reached by applying to the servo any continuous input $r(t)$.), the output $c(t)$ will be bounded for all t (including sampling instants) if 1. $G(s)$ has left half-plane poles and only one simple pole at $s=0$ with a positive residue, and 2. the degree of the numerator polynomial is at least one less than that of the denominator polynomial.

Note that the statement does not make any particular assumption regarding the shape of the amplifier-gain characteristic except that it is single valued and that it saturates, i.e., as $E(n)$ becomes large the amplifier output $h(t)$ becomes equal to $\pm H_0$, the saturating level of the amplifier, more precisely when $|e(t)|\geq E_0$, $h(t)=e(t)/|e(t)|\,H_0$.

The proof follows. If $g(t)$ is the unit impulse response of $G(s)$, then

$$c(t)=\int_{-\infty}^{+\infty}h(\tau)g(t-\tau)d\tau$$

Let p be the degree of the denominator polynomial of $G(s)$. Differentiating this expression k times with respect to t,

$$c^k(t)=\int_{-\infty}^{+\infty}h(\tau)g^k(t-\tau)d\tau \quad k=1,2\ldots p-1$$

where $g^k(t)$ denotes the kth derivative of $g(t)$ taken in the distribution sense[2] so that it may contain impulses, doublets, etc., at $t=0$. As a result of the piecewise continuous character of $h(\tau)$, the aforementioned equality may not have a meaning where $k\geq 2$ for $t=nT$ because distribution theory does not define the integral of an impulse times a function that is discontinuous at the impulse. In view of the assumptions on $G(s)$, $g(t)$ is of the form

$$g(t)=A+\sum_k\left(\sum_l A_{kl}\frac{t^l}{l!}\right)e^{p_k t} \tag{49}$$

where $Re(p_k)<0$ for all k's, hence all its derivatives are absolutely integrable, in particular,

$$\int_{-\infty}^{+\infty}|g^k(t)|dt<M_k \quad (k=1,2\ldots p-1)$$

where M_k is an appropriate positive constant. Since for all t, $|h(t)|\leq H_0$ we have

$$|c^k(t)|\leq H_0\int_{-\infty}^{+\infty}g^k(t-\tau)d\tau$$

and

$$|c^k(t)|<H_0M_k \quad (k=1,2\ldots p-1)$$

the inequality being valid for all t if $k=1$ but may not be valid at sampling instants for $k\geq 2$. It should be stressed that the uniform boundedness of all derivatives of the output $c(t)$ (except possibly at sampling instants) follows from the fact that $G(s)$ contains a single integrator and that its other poles lie inside the left-half plane.

It remains to show that $c(t)$ itself is uniformly bounded. If it can be proved that the servo cannot remain in saturation for a time longer than T_1 (where T_1 is a constant independent of the initial conditions and dependent only on the characteristics of the servo) then, the already proved boundedness of $\dot{c}(t)$ implies that $c(t)$ is bounded. In particular

---

* The results reported here came from research supported by the U. S. Air Force through the Air Force Office of Scientific Research of the Air Research and Development Command, under Contract no. *AF18(600)-1521*.

$$|c(t)| < E_0 + H_0 M_1 \frac{T_1}{2}$$

This inequality follows from the following geometric argument: When the servo enters saturation, $c(t) = E_0$. (Here we assume positive saturation; in case of negative saturation $c(t) = -E_0$ but the remainder of the argument follows with a few trivial changes.) The existence of T_1 means that during the following T_1 seconds the servo has come out of saturation. Therefore the largest excursion of $c(t)$ would occur if $c(t)$ would increase at the maximum rate for $T_1/2$ seconds and decrease at the maximum rate for the remaining $T_1/2$ seconds.

It remains to establish the existence of time T_1. Suppose the servo enters saturation $(c(t) > E_0)$ in the interval $(m-1)T < t \leq mT$ and is still in saturation at $t = mT$, then $c(mT) < E_0 + H_0 M_1 T$ since the slope of the curve $c(t)$ is always smaller than $H_0 M_1$. Thus, as long as the servo remains in saturation the following situation exists: 1. the input to $G(s)$ is $-H_0$, and 2. the initial values just after the sampling instant mT are such that $E_0 < c(mT) < E_0 + H_0 M_1 T$, $|c^k(mT+)| < H_0 M_k (k = 1, 2. \ . \ . p-1)$. The solution of the differential equation indicates that as long as the servo is in saturation and $t > mT$

$$c(t) = \sum_{k=0}^{p-1} c^k(mT+)\psi_k(t-mT) - H_0 \int_{mT}^{t} g(\tau - mT) d\tau \quad (50)$$

The pole locations of $G(s)$ require that the transients $\psi_k(t-mT)$ are of the same form as the right hand side of equation 49.

Therefore the function

$$f(t) = \sum_{k=0}^{m-1} c^k(mT+)\psi_k(t-mT)$$

is uniformly bounded for all $t > mT$ by a constant M which is independent of the initial conditions since the latter are uniformly bounded. Now, equation 50 cannot hold for arbitrarily large t since the integral $\int_{mT}^{t} g(\tau - mT) d\tau$, for large enough t, increases linearly with t. As a consequence $c(t)$ given by equation 50 will eventually become smaller than E_0 and the servo will come out of saturation. The time the servo will remain in saturation will be bounded above by $T_1 = T_0 + T$ where T_0 is the smallest number x such that

$$\int_0^x g(\tau) d\tau = \frac{M - E_0}{H_0}$$

From this expression it is apparent that T_1 depends exclusively on the characteristics of the servo and is independent of the initial conditions.

In short, it has been shown that, except maybe at the sampling instants $t = nT$, the phase-space point $[c(t), \dot{c}(t), \ddot{c}(t) . \ . \ . c^{p-1}(t)]$ remains inside the parallelpiped defined by the following inequalities

$$|c(t)| < E_0 + H_0 M_1 \frac{T_1}{2}$$

$$|c^k(t)| < H_0 M_k \qquad (k = 1, 2 . . . p-1)$$

These inequalities hold whatever might be the initial conditions. The only thing that was proved was the boundedness of $c(t)$ and its $(p-1)$ first derivatives. This does not imply that the servo is asymptotically stable which would require proving that $c(t)$ and its $(p-1)$ first derivatives go to zero, as $t \rightarrow \infty$.

Francis J. Mullin: The author would like to thank Professor Desoer and Mr. Kodama for their discussion and certainly agrees with their results; namely, that if the sampled-data system shown in Fig. 1 contains a saturating element and $G(s)$ is a transfer function with *one* integrator and all of its remaining poles in the left-half s-plane, then the continuous output of the system is bounded for all time. This is in contrast to the statement in the paper which permitted $G(s)$ to contain $(p-1)$ integrators and still have a bounded output. This statement in the paper of the restrictions on $G(s)$ is incorrect. $G(s)$ may contain only a single integrator if the output of the saturating system is to be bounded.

The proof for the boundedness of the output which the discussers have presented is both understandable and clever. The idea of showing that the system cannot remain indefinitely in saturation is the key to their argument and the fact that this is true, definitely shows the boundedness of the output.

The argument which was originally used to show the boundedness of the output was based on the difference equations which describe the sampled-error signal. The sampled-error signal was expressed as a combination of sampled derivatives of the error signal and since all derivatives are bounded, it was believed the sampled-error signal was bounded. This is true only if $G(s)$ is a stable transfer function with a single integrator. If this condition is not satisfied, then it is not possible to express the sampled-error signal in terms of the derivative quantities because some coefficients of the difference equations are identically zero. This fact was overlooked in reference 6. At any rate, the question on the boundedness of the output of the system in Fig. 1 has been cleared up by the discussion and the author appreciates the efforts of the discussers and this contribution.

Synchronous Methods of Operation for Private Telegraph Networks

B. S. DIAMOND
MEMBER AIEE

THERE ARE MANY private telegraph networks in the United States serving industrial, commercial, financial, and transportation organizations, and used for the transmission of intracompany message traffic, data transmission, and telemetering. In size there is a wide range, from small networks with a home office and a single branch, to large and highly complex ones with tens of thousands of miles of facilities, hundreds of operating points, and weekly message files running into six figures. The majority of private networks lease both equipment and facilities. However some own their operating equipment and lease facilities, while others own both equipment and the plant that provides the facilities.

Most trunk circuits are routed via voice-frequency channels with either 150 or 170 cps (cycles per second) allocated to each channel. There are, however, a number of radio circuits and a few physical lines of moderate length. Local drops are usually metallic loops.

The standard method of operation is start-stop at either 60, 75, or 100 wpm (words per minute). The exceptions include some leased multiplex channels, an occasional morse circuit left over from the past, telautographs or facsimile for certain types of local service, and a few wide-band installations for data transmission. The advantages of start-stop operation are obvious. Installations are easy to make, convenient methods of switching are available, maintenance and planning problems are relatively simple, and, when traffic loads are light, ordinary typists can take the place of professional telegraphists.

In areas where lines or facilities are cheap, plentiful, and efficient, start-stop is undoubtedly the preferred method of operation. On the other hand, where circuits are costly, and accuracy and

Paper 59-61, recommended by the AIEE Radio Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1-6, 1959. Manuscript submitted October 14, 1958; made available for printing November 25, 1958.

B. S. Diamond is a telegraph consultant, Madison, N. J.

efficiency are important factors in the operation of long-distance trunks, synchronous methods may be preferable.

The purpose of this paper is to show that private networks may be able to obtain significant advantages by the use of synchronous methods on expensive trunk circuits and on circuits subject to transmission difficulties.

Comparison of Transmission Features

Possible Disadvantages

In comparison with synchronous methods start-stop has disadvantages, which can be quite serious, on trunk circuits where accuracy, efficiency, and costs are factors of importance. Consider the following:

Tolerance for Distortion

Under the most favorable circumstances for either method of operation, a start-stop receiver has only one half the tolerance for distortion possessed by a synchronous receiver. Practically, the differential is nearer three to one because of the necessity of providing, in start-stop working, for a possible difference of 1% between rate of modulation and rate of receiver selection, and for unavoidable suboptimum adjustments of start-stop operating equipment.

Accuracy

In the case of a medium subject to characteristic distortion plus interference, the total amount of telegraph distortion, as discussed in the Appendix I, may be more than twice as much as would be apparent with characteristic distortion alone. Where there is more than one source of interference, there is a tendency for an isolated "pile-up" to occur. If a pile-up of, say, 20% signal amplitude coincided with a crossover, and with a discrepancy between rate of modulation and rate of receiver selection, an error is liable to occur, particularly if there are any significant suboptimum adjustments of the operating equipment.

When trunk circuits are lengthy, and comprise two or more sections in tandem, the error-rate may be quite high. In one network where circuits were normally complex because of the switching system, observations indicated an error-rate of one per 1,000 characters. In many error checks observed by the writer on complex chains, comprising both start-stop and synchronous links, the majority of errors occurred on the start-stop links.

Code Efficiency

Except where crypto operation is required, synchronous operation normally requires 5 units only per character as compared to the 7.42 cycle of start-stop.

Efficiency of Utilization

With synchronous operation as a reference, start-stop will normally have an efficiency factor of less than 50% even on voice-frequency channels specifically designed for start-stop operation.

Through other media, because there is a choice of but three modulation rates with start-stop, the efficiency of utilization may be quite low. If the characteristics of a transmission channel are such that a modulation rate of 45.45 bauds is not practicable, there is not even a circuit if dependent on normal start-stop methods.

On the other hand, there are no definite lower or upper limits for synchronous operation. Present-day modulation rates range from a low of probably 9 bauds to a high of 300 bauds. At least one modern synchronous system is potentially capable of 16 channels at 100 wpm per channel which, with 6-unit operation, would result in a modulation rate of 960 bauds.

Table I. Wpm for Various Modulation Rates

Modulation Rate, Bauds	Pulse Length, Milliseconds	Wpm 5 Unit	Wpm 6 Unit	Wpm 7 Unit	Wpm 7.42 Unit	Wpm 8 Unit

* Rate for nominal 60 or 65 wpm, start-stop.

† Rate for nominal 75 wpm, start-stop.

‡ Rate for nominal 100 wpm, start-stop.

The telegraph companies and the armed forces of the United States do not consider the operation of major overseas trunks to be either satisfactory of efficient with start-stop methods and generally these are operated synchronously.

Private telegraph networks do not have the direct economic and operational pressures that make the telegraph companies and the armed forces operate their circuits with optimum efficiency. Where facilities are plentiful and cheap, an abstract utilization efficiency factor means little; where reliable, the advantage of synchronous equipment in working through adverse conditions is not so important.

However, the facilities used by private networks cannot always be considered as being either cheap or plentiful. The cost of a 1,000-mile lease is not low and, while it may normally be possible to lease a 61-wpm start-stop facility between almost any two cities in Canada and the United States, there could be considerable difficulty in getting one suitable for 100 wpm, start-stop; see Tables I and II.

Neither are private networks always free of adverse transmission conditions. In making the survey for this paper, two comments on the difficulties of working start-stop through heavy interference from power mains were heard and it may

Table II. Utilization Factors

Type of Circuit	Wpm	Band Width, Cps	Utilization Factor
Standard telegraph voice-frequency carrier channels	65	120	0.54
	75		0.625
	100		0.83
	65	150	0.43
	75		0.5
	100		0.67
	65	170	0.38
	75		0.44
	100		0.59
Ocean cable carrier, reference circuit between Newfoundland and Nova Scotia with normal signals	65	50	1.3
Ocean cable carrier, reference circuit between Newfoundland and Nova Scotia with suppressed singles	83.3	50	1.67
Ocean cable physical, normal signals	300	113	2.65
Ocean cable physical, suppressed singles	300	60	5.0
Ocean cable physical, 3-element cable code	50	11.6	4.3

For comparing utilization efficiencies of transmission channels, the rate of speed may be divided by band width. Dividing wpm by the band width in cps provides a convenient set of reference figures to indicate relative efficiency as far as the movement of traffic is concerned. This figure may be called the utilization factor.

be assumed that these were not isolated. Transmission channels derived from radio beams are sometimes so seriously afflicted with atmospherics and multipath effects that communication with normal start-stop methods of operations is submarginal.

Possible Advantages

Some examples of situations where private networks might gain significant advantages from synchronous equipment follow:

Where Faster Trunk Circuits Are Required

If a transmission channel has a rating of 45.45 bauds, start-stop, and telegraph distortion is no greater than 10%, synchronous operation at a modulation rate of 74.2 bauds should be practicable and the following working speeds possible:

Units	Wpm
5	148
6	123
7	106
8	93

If the channel has more than 10% distortion but is still error-free when working start-stop, a modulation rate of 56.88 bauds should be possible and the following speeds obtained:

Units	Wpm
5	114
6	95
7	81
8	71

The above estimates are based on actual experience with multiplex circuits routed via transmission channels set up for 45.45 bauds, start-stop.

For transmission channels having a rating of 75 or 100 wpm, start-stop, the amount of gain possible from synchronous operation will depend on the efficiency of intersection couplings plus the amount of interference within the transmission channel. Such channels are normally space the same as those with a rating of 61 wpm and the higher speed obtained by circuit refinements. Hence, the gain from a changeover to synchronous operation is unlikely to be as great proportionately as on a channel with a rating of 61 wpm.

Where, Without Necessarily Suffering from Congestion, Channels Are Required for Traffic Routing Purposes

With this problem, advantage could be taken of the characteristic ease and reliability of channel splitting, character by character, of synchronous methods of operation. At the same time, a worthwhile increase in speed may be obtainable. Possible channel speeds and patterns are shown in Table III.

Where Circuits Are Subject to Interference from Power Mains

Consider the case of a circuit subject to interference from power mains to the extent that normal start-stop working was impossible. The working band for a 61-wpm start-stop circuit normally extends to a frequency between 50 and 70 cps. Hence, discriminatory networks will be of little value unless the amount of characteristic distortion present was small.

On the other hand, a 60-wpm 6-unit synchronous circuit will have a modulation rate of 38 bauds and only requires frequency components extending to 27 cps. With over an octave of clearance, a 6-db (decibel) improvement in signal to interference ratio could be anticipated with a capacitance of suitable value, 12 db with a simple L/C (inductance capacitance) network, and, as far as the mains frequency was concerned, probably up to 40 db with a more complex filter although, with over 20 db attenuation on the mains frequency, low-frequency transients, from variation on the mains load, might become prominent.

As an example, it was found, in laboratory experiments, that a synchronous circuit at 45.45 bauds was free of errors 60-cps interference superimposed on a signal having about 25% characteristic distortion. The amplitude of the interference was about 25% that of the signal; total distortion was about 60%. Given a similar situation in the field, a circuit with a total of 60% telegraph distortion would not have been considered safe for traffic. However, with a simple filter, the interference could be reduced by nearly 12 db to a residue of, say, 8% signal amplitude. The total distortion would then have been reduced to, possibly, 40% and, worked synchronously, the circuit would have been a solid one.

Where Circuits Are Subject to Interference from Atmospherics and Multipath Effects

On a radio link, multipath effects and atmospherics may make straight start-stop operation unsatisfactory. Where this occurs, heavy filtering with well-damped networks, plus synchronous operation, may convert an unsatisfactory circuit into a good one. In extreme cases, where it could be justified economically and suitable technical personnel was available, most of the errors could be eliminated by an automatic "RQ" system. Theoretically, provided that minimum signal amplitude was adequate, interference can be integrated and a circuit obtained at some speed which, of course, could be on the low side.

Table III

Modulation Rate, Bauds	Code, No. of Units	Two Channels, Wpm	Three Channels, Wpm	Four Channels, Wpm
56.88	5	57.0	37.9	28.4
	6	47.4	31.6	23.4
74.2	5	73.2	49.5	39.5
	6	61.8	41.2	31.2

Equipment Problems for Private Networks

Any advantages that private networks might obtain in theory from the use of synchronous equipment are not of much practical use unless suitable equipment is available. Hence, some design criteria should be developed.

Until the pressure of circumstances stimulated development work in synchronous techniques during the late 1940's and early 1950's, multiplex sets had certain drawbacks. Rotary distributors were driven from fork contacts and fork frequencies were none too stable. Synchronism was obtained by stepping the brush-arms with mechanism that was seldom completely reliable and which frequently either missed or took double jumps. A transitory bias might cause a rush of corrections that could result in an out-of-phase. A gap of a few seconds would also result in an out-of-phase. When, on domestic lines, large numbers of relatively inexpensive voice-frequency telegraph channels became available for start-stop working, the old multiplexes were discarded.

Later, the increase in volume of overseas message traffic and the demand for leased channels, concurrent with the general adoption of frequency-shift keying methods on radio and the repeaterization of long submarine cables, stimulated developments in synchronous techniques and time-division multiplex.

As a result, modern multiplex equipment is very different from that in use prior to World War II. Frequency control and synchronizing networks are now electronic with a great improvement in stability. Out-of-phases, because of speed variation and short gaps, no longer occur. The use of 5-wire printers for traffic reception has been generally discontinued and local loops, both sending and receiving, are mostly start-stop.

Fig. 1. Test regenerator

For coupling purposes, the modern multiplex channel is every bit as flexible as a start-stop one and possibly more convenient for certain methods of automatic switching.

However, the increasing emphasis on electronic methods has sometimes resulted in a tendency for complexity to increase and some of the more recent multiplexes, for one of which the writer has to accept responsibility, contain hundreds of electronic elements such as vacuum tubes, diodes, and transistors. With such complex equipment, a great deal of theoretical knowledge, experience, and study, together with ample patience and time, may be necessary to localize and clear an obscure dry joint, faulty connection, or defective circuit element.

Equipment of this type may be beyond the understanding of the most useful type of technician, the type indispensable for keeping a system running. That is, the good practical man with years of experience, who knows telegraph routine, has sufficient operating ability for, at least, the exchange of service messages, can maintain printers, and who has some technical training superimposed on a high school education.

To be of optimum value to private networks, synchronous equipment should be designed on the assumption that it will be in the hands of men with the knowledge, time, and experience required for the care of reasonably simple electronic circuitry but who might have difficulty with highly complex networks.

Methods of Operation

For single-channel synchronous operation, 5- or 6-unit operation would involve storage and the use of a translator for conversion from or to start-stop signals. If simplicity of equipment is considered to be an important factor, 7-unit operation, with start and stop pulses transmitted, might be considered preferable.

For single-channel 7-unit synchronous operation, rate of transmission would be controlled by a stable frequency with, at the receiving end, a synchronous regenerator followed by a teleprinter.

The normal 7.42 cycle is obviously impossible with a simple synchronous regenerator. However, the only reason for the prolonged stop pulse is to provide margin against, first, a possible speed differential between sending and receiving ends and secondly, line distortion. When the speed is stable and distortion cannot reach the printer, 7-unit operation should be satisfactory.

With 7-unit operation, a 60-wpm printer will work at 65 wpm; 75-wpm one at 81.2 wpm, and the 100-wpm type at 106 wpm. Unless carefully adjusted, the older types

may not have quite enough margin for 7-unit operation at 100 wpm but the Model 28 has ample if signals are reasonably free of distortion. On a transmission line with a 60-wpm start-stop rating, 7-unit synchronous operation at 81.2 wpm should be quite reliable and 106 wpm may be possible.

Synchronous regenerators are old in the telegraphic art and a number of excellent ones were developed years ago. With a modern synchronizer, any of these would be suitable for 7-unit synchronous operation. The simple regenerator used by the writer in transmission experiments is shown in Fig. 1. While not as good as some of the others under traffic conditions, it has the advantage that input, transfer, and output meshes are independent of each other.

In considering methods of multichannel operation for private networks, it should be noted that the most complex, expensive, and troublesome sections of modern multiplexes are those that translate between the multiplex code and start-stop. Where simplicity of equipment and ease of maintenance are factors of importance, the use of translators could be made unnecessary by 6-unit operation, with start pulses transmitted, at the same rate of modulation as one of the start-stop rates. One method of doing this is shown in Figs. 2(A) and 2(B). Experience with this type of multiplex indicates that it is most reliable, with minimal maintenance problems, and that it is popular with technicians.

As the switching operations of the circuits of Figs. 2(A) and 2(B) are relatively simple, the electronic circuitry required for replacing the rotary distributor would be relatively simple. Ring counters or reliable decade switching tubes are obvious possibilities.

SYNCHRONISM

The heart of any synchronous system is the method used for maintaining optimum time relationship of the receiver with the incoming signals. Any synchronous operation on the part of private networks will probably be almost entirely point-to-point with nothing resembling the complex chains set up by the communication companies. Therefore synchronizing problems should be simpler.

At receiving points, the use of highly accurate but complex time bases would probably be undesirable because of expense, complexity, lack of range, and sluggishness in falling into phase. A relatively simple, inexpensive, and flexible arrangement would be preferable.

At the sending end, a reasonable degree of accuracy and stability would be required; say, an accuracy of one part in 500 and a stability of one part in 10,000. At the receiving end, there should be a range of about 1% for setting the basic frequency, and the synchronizer should be able to maintain optimum time relationship with a change in relative speeds of about one part in 2,000. If signals are cut off, the receiver should not shift phase significantly over a period of a few minutes.

It is probable that methods now in use by the communication companies could be adapted to meet these requirements.

PERFORMANCE SPECIFICATIONS

To meet the needs of typical private telegraph networks, performance specifications should include the following points:

1. Circuitry should be kept reasonably simple so that it can be understood by available technicians.
2. Equipment should be capable of running for some months without servicing; maintenance should not require the services of highly skilled specialists.
3. Where suitable, for the sake of simplicity and ease of maintenance, the modulation rate should be at one of the start-stop rates, that is, 45.45, 56.88, or 74.2 bauds, or some multiple of one of these rates for multichannel circuits.
4. Sending-end frequency accuracy should

be one part in 500 and over-all stability one part in 10,000.

5. At the receiving end, frequency should be adjustable over a minimum range of 1% and the synchronizing circuitry capable of maintaining a constant selection phase with a relative speed drift of one part in 2,000.

6. For multichannel equipment, channel phasing should be semiautomatic on idler signals and in unit element steps on mixed signals.

Conclusions

Private networks might gain significant advantages from the use of synchronous equipment under the following circumstances:

1. Where higher speed trunk circuits are required.
2. Where extra channels are required but are not otherwise available, or costs are high.
3. Where circuits are unstable because of factors such as variable amplitude, interference, and excessive distortion, and where the error rate is high with normal start-stop operation.

It is doubtful if private networks, with some exceptions, could make effective use of the highly complex and expensive synchronous multiplex equipment in general use by the communication companies and the armed forces. For general use in private networks, equipment should be relatively simple and straightforward, easy to maintain, and the price should be equitable.

Although reference was made in this paper to synchronous methods used by the various communication companies, it was not possible to supply much in the way of specific information on such methods. Those interested in a comparison of multiplex techniques may wish to consult the list of references.

Appendix I. Distortion

Telegraph Distortion may be defined as the deviation in the timing of a received transition, after signals have passed through a limiter, relay, flip-flop, or saturated grid, as the case may be, from that of an ideal signal.

Any one transition can have but one value of distortion. Hence, to have meaning, telegraph distortion must be observed over a period of time and expressed as the ratio of the sum of maximum negative and positive deviations observed against the time of a unit element. For example, if the time of a unit element was 20 milliseconds, and the maximum transition variations observed were 2 milliseconds early and 2 milliseconds late, with reference to the center of the transition band, the distortion would be 4/20, or 20%.

On synchronous circuits, the timing reference may be derived from the instrumental time base, which is normally synchronized by an integration of received transitions, or from a stable independent oscillator. On start-stop circuits, the transitions of the selecting pulses, and front transition of the stop pulse, are matched against the beginning of the start pulse.

Sources of Telegraph Distortion

Characteristic Distortion. This is a function of the transmission medium. It can be observed directly only before a signal passes through a limiter and has several facets which include:

1. Asymmetric distortion which is indicated by a transition having a different shape when going from mark to space than when going from space to mark. It is caused by nonlinearity in amplifiers and inductances. Asymmetry is difficult to avoid on any signal that is passed through an amplifier.
2. Short sways which may be derived from the transient components of the signals, or from a tendency for flats to build up or fall away. This effect frequently results in the first element after a flat being too thin or too fat.
3. An exponential rate of change on transitions between mark and space which may be relatively fast on a wide-band circuit and slow on a narrow-band one. Susceptance to sways, asymmetric distortion, interference, and biases is normally inversely proportional to this rate of change and it is probably the most important factor in determining circuit margin.
4. Phase distortion which may be manifested by an overshoot on a transition, or by "broken-back" double and triple element flats.

Interference. On physical lines, interference from power circuits is usually the worst offender, with cross fire from adjacent telegraph circuits a close second. Interference of this type is most frequently developed in common earth impedances. On voice-frequency carriers, cross fire from adjacent channels or other circuits may often be observed. Sometimes interference from power mains is significant. On radio circuits, atmospherics and cross fire from other circuits are usually the dominant sources.

Transitory Biases. These may be due to variation in signal amplitude or by voltage variations in amplifiers.

Keying Losses. The amount of telegraph distortion from this source will depend on the value of n per $2f$, where n is the rate of speed in bauds and f is the carrier frequency in cps. If the value of n is 100 bauds, and f 500 cycles, the keying loss would be 10%. However, if f were 5,000 cps, the keying loss would be only 1%. With amplitude modulation, keying losses can be reduced to zero by synchronizing signals and carrier frequency.

Clipping. Where relays are used in "on-off," or nonpolar coupling, some clipping is difficult to avoid on either mark or space because of relay transit time. The effect may be caused by relay transit time being either under or over compensated.

Additional factors, equivalent to distortion, but applicable to start-stop only:

Motor Differential. When the respective drive motors of the sending and receiving machines are synchronous, and the driving power is derived from independent supply systems, there will be some difference between rate of modulation and the rate at which the receiving printer selects. Where governed motors are used, this is not an uncommon source of trouble.

Instrumental Maladjustments. On the sending side, distortion may occur from an inaccurate cam assembly or from a poor brush condition on a face-plate. On the receiving side, it is rare to find optimum adjustments on a start-stop printer.

On local circuits, there is no significant distortion and on such service the start-stop receiver is ideal, giving minimum trouble with a very low error rate. On trunk circuits, all of the listed factors may be present and, for start-stop operation, margin has to be provided for motor differential, instrumental maladjustments, clipping, and keying losses; this leaves little margin for adverse transmission conditions which include transitory biases, interference, and characteristic distortion. Hence, the error rate, with a start-stop receiver, is apt to be high on long-distance circuits.

On the other hand, with a synchronous system there is no problem of speed differential, and instrumental maladjustments and clipping will be insignificant if polar couplings are used throughout. Hence, practically all of the margin of a circuit operated synchronously can be used to override characteristic distortion, interference, and keying losses. On a long-distance circuit, the error rate should be insignificant for as much as 40% distortion.

Discussion

R. S. Wishart (Western Union Telegraph Company, New York, N. Y.): For 45 years Western Union has been a great user of synchronous methods of operation and none of us will question Mr. Diamond's thesis that such methods have an advantage over start-stop in the face of disturbance that will interfere with operation of the latter. We also use synchronous methods on cables, where usable frequency spectrum is limited and the maximum capacity must be obtained. High-speed data circuits are another case where synchronous methods may be used.

Nevertheless, there are many good reasons for using start-stop operation where plant facilities are relatively free of disturbance and constantly under observation for control of interference and bias.

The paper did not indicate whether the comments were directed at wire and radio telegraph networks owned by individual corporations such as pipe lines, railroads, etc., or whether the references were to private wire systems furnished to others by Western Union and American Telephone and Telegraph Company. Several of the statements supporting synchronous application, therefore, require discussion. Some of them were evidently based on conditions prior to the recent increased availability of 100-wpm teleprinter equipment and facilities to go with it.

If we consider the application of synchronous methods to the Western Union private-wire systems, we are faced with certain problems. More than half of our leased facilities are used as part of switching systems and a considerable portion of the remainder are way station circuits at various speeds and using "hub" type repeaters. A majority in number of the switching systems are of a single switching center type with long way circuits extending from the switching center. Even where there are multiple switching centers, these individual centers serve their areas with way circuits. These way circuits are duplex circuits carrying control signals in both directions. These carefully planned switching and way wire systems are not susceptible of operation by synchronous means in the present state of the art.

There is a constant tendency to increase the speed of way circuits and trunks from 65 to 75, and then to 100 wpm as load increases; contrary to Mr. Diamond's statement it is not difficult to obtain 100-wpm circuits. There is often economy in the higher speed because more stations may be added to a way circuit without greatly increasing the wire mileage paid for. In addition, if one way circuit has been cancelled by shifting its stations to the one with increased speed, positions in the switching center are reduced.

Our 65-, 75-, and 100-wpm circuits are obtained from 150-cycle carrier channels. This provides flexibility compared with the fixed speeds of any particular synchronous system.

Mr. Diamond states that when trunk circuits are lengthy, and comprise two or more sections in tandem, the error rate may be quite high and that in one normally complex switching network, observations indicated an error rate of one per 1,000 characters. He also observes that in many error checks on complex chains comprising start-stop and synchronous links, the majority of errors occurred on the start-stop links.

This condition does not register with me as fitting a Western Union situation. In the first place, we have determined that on our carrier channels and short single wire extensions the following are safe limits on numbers of sections without regeneration:

Speed in Wpm	No. of Sections
65	6
75	5
100	3–4

One or more of these sections may be a physical wire. Channels derived from radio beam systems are included in this calculation, and we can regenerate new signals and continue the expansion to any size network we desire.

As to accuracy, notwithstanding many over-all and sectional tests in our public message and customer's private wire systems, we cannot substantiate an average error rate as bad as one per 1,000 characters. Comparing originating tapes, relay tapes at switching centers, and terminal copies, in a typical large customers' switching system, having several switching centers, we found that the various links each produced 99+% message accuracy and that the origin-to-destination percentage of perfect messages transmissionwise was 96%. In this study, corresponding originating and terminating tapes were compared with each other by means of comparing transmitters and page copies were made from original tapes and compared with terminal copies. A very exact listing of errors incurred during transmission was obtained. Few of the errors could be attributed to the transmission medium. As a result of analysis, equipment faults in the transmitters, perforators, and reperforators were considered to be the cause of most errors.

As engineers, we are not satisfied with this degree of accuracy and don't boast about it, but in switching systems there is at present considerable difficulty in quickly catching a source of error.

As you know under the older systems of operation, complete circuits were operated from terminal to terminal and messages were subject to constant scrutiny at the terminal points. The occasional facility or equipment difficulties which occurred even on the highest class circuits with good maintenance came to light very quickly and were remedied. These same good circuits, when assembled into a switching system, are likely to produce many more of the occasional type error because the switching operators and the mechanical devices now only scrutinize the routing section and sequence numbers of messages. Under such conditions the errored messages become scattered as they are switched and there is no concentrated scrutiny of the messages on each section to catch a minor failure. Such minor failures might be a sticking pin in a transmitter or sticky operation of a selector bar in a reperforator, or a momentary fault in a facility for instance. If error-checking devices can be economically inserted in such systems the error-frequency rate will be drastically reduced.

When we look at records of circuits it is remarkable how many of them are error-free for long periods of time. With our rapid changeover to voice-frequency channels and paired facilities, the Western Union system is now only slightly effected with disturbance from power mains. It is quite different from the old days.

Mr. Diamond comments that transmission channels derived from radio beams are sometimes so seriously afflicted with atmospherics and multipath effects that communication with normal start-stop methods of operation is submarginal. This comment may be accurate as regards some types of radio beam circuits but it does not agree with our findings on Western Union beam circuits. They were specifically designed for telegraph operation with space diversity reception in the older installations and frequency diversity in the newer installations. While there are some residual multipath and fading effects during periods in the summer, they occur after midnight and have cleared by 8 a.m. and have little effect during general business hours. Our 12 years' experience in operating these radio beam circuits indicates that very little more work is needed to reduce the fading troubles to a negligible value. We are reaching a point where equipment outages and "hits" on intracity and office cables outweigh propagation failures.

We don't question the value of synchronous methods in certain difficult transmission conditions or where desired capacity can be obtained in no other way, and we will certainly use that tool when it is required. Actually some 25% of our channels between switching centers in the public message system are derived from synchronous multiplexes operating over 150-cycle carrier channels. This is a rugged, partly electronic, synchronous multiplex designed for the purpose of connecting to start-stop printers and gives good service. We have studied the possibility of expanding this use by developing entirely electronic systems, but the economics of obtaining channels this way as against more 150-cycle carrier channels have not proved satisfactory. The field for increased use of synchronous multiplex in the public message system is not large, when we consider the desirability of distributing channels between cities into alternate routes for protection of service.

Our Western Union facilities are now so stable that we care very little whether synchronous or start-stop operation is applied to the derived telegraph channels. The results are equally good.

B. S. Diamond: Mr. Wishart's comments are very informative and the only point on which there seems to be any serious difference of opinion between us is on error rates.

Error rates on circuits operated by public telegraph systems are unquestionably low. However, support for my observations that it is high in, at least, some private networks is provided by a passage in the *Proceedings* of the Association of American Railroads, May 1958, page 258, which reads:

> Messages normally consist of words which are interpreted by people. Errors in spelling or spacing are often obvious and result in no loss of intelligence. Even when figures are involved, the intelligence of the message may not necessarily be impaired by errors. Because of human ability to judge and interpolate, error rates as high as 1 in 100 are *often* economically acceptable on message circuits.

A Generalized Computer Procedure for the Design of Optimum Systems—Part I

R. RODERICK BROWN
ASSOCIATE MEMBER AIEE

CONVENTIONAL design techniques cannot readily produce optimum solutions to present-day design problems. The ideal characteristics of a design procedure are reviewed herein and compared with the conventional techniques. The characteristics of a currently feasible procedure are noted, and a new technique for use with a digital computer is described. A sample design optimization is employed to illustrate the operation of the new technique, which closely approaches the ideal design procedure.

Characteristics of a Design Procedure

The objective of any system design procedure is usually twofold. First, a design which meets the specifications and other constraints imposed upon the system must be produced. Second, this design should concurrently be optimum with respect to some criterion (cost, weight, etc.). The criterion used to define the optimum system will, of course, depend upon the particular application under consideration. For example, the optimum electric generating system for aircraft is usually defined as the lightest-weight system which meets the specifications, i.e., this system is optimum with respect to weight. For clarity in the ensuing discussion, an optimum design will be defined as the design which simultaneously meets the specifications and is optimum with respect to some criterion, and an acceptable design (i.e., a feasible solution) will be defined as any design which meets the specifications.

The characteristics of the ideal design procedure may now be enumerated. In particular, the procedure should: 1. produce the optimum design, 2. be efficient, 3. be versatile, 4. be accurate, and 5. be currently feasible and economical.

The first requirement is clearly desirable whenever the system is to be manufactured in quantity or is to be used in critical applications. The requirement that the procedure be efficient (i.e., produce a design rapidly) is highly important in competitive fields, and is receiving continual stress in both the military and commercial areas. The requirement of versatility is intimately connected with that of efficiency, for a design procedure independent of both system configuration and complexity will necessarily eliminate the need for adapting it to fit the particular problem under consideration. It is the author's viewpoint that the greatest over-all efficiency will be achieved by utilizing a generalized procedure, as opposed to developing special techniques for each genus of problem. It should be realized that this viewpoint is conjectural, and can be substantiated (or disproved) only by an accumulation of considerable practical experience with both approaches. The requirement of accuracy is fundamental, for the design process would be worthless if the results of its application were not closely related to the physically realizable system. Lastly, the requirement that the procedure be currently feasible and economical is essential if it is to be both immediately useful and practical.

It will become clear from the ensuing discussion that it is presently impossible to realize the ideal procedure. However, it is possible to realize a technique which closely approaches it. Such a technique is described herein. To provide a basis for comparison, it is worth while to describe the conventional design technique and compare it with the ideal.

The Conventional Design Procedure

The conventional procedure for producing an optimum system design is a trial-and-error process involving two overlapping steps. First, an acceptable design is produced. The trial-and-error process consists of choosing certain reasonable values for the design variables (i.e., the physical parameters of the system) and then computing the performance parameters, which are compared with the specifications. Discrepancies between the latter are then eliminated by changing the design variables appropriately. After several variations in the design have been made, the specifications will be satisfied, thus yielding an acceptable design. The second stage of the procedure may now be undertaken. Such additional variations in the design are made that it approaches the optimum more closely. In this manner a series of acceptable designs are made, the best of these being selected as the "optimum."

Clearly, the best of the acceptable designs produced is not necessarily the optimum, or best possible. Indeed, only if an exhaustively large number of designs is produced can there be any confidence that the best available is the optimum. Generally, economic reasons preclude the determination of many designs, with the result that, in practice, the conventional technique does not produce the optimum design.

The choice of the appropriate parameter variations to be made during the design process must, in general, be made by the individual designer. Thus the time required to achieve an acceptable design is determined by the designer's previous experience with and his insight into similar system configurations. Consequently, the procedure will be relatively inefficient when applied to new systems. A further consequence of the need for experience and insight is that the process lacks versatility, for the choice of parameter variations appropriate for one system is unlikely to be appropriate for another. In addition, the design of highly complex systems is usually accomplished by making certain simplifying assumptions, which assuredly increases the efficiency of the technique, but usually also reduces the accuracy of the final results.

It may be noted that current design techniques have capitalized upon the high computational speed of digital computers to effect improvements in the efficiency of the conventional procedure. Indeed, in certain cases, it has been possible to code the computer so that it will automatically produce an acceptable design. Examination of these techniques shows that they fall within the broad category of the conventional procedure and must be considered primarily as implimentations thereof.

It is apparent that the conventional design technique does not fulfill the requirements of the ideal procedure. The

Paper 58-234, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted October 25, 1957; made available for printing November 13, 1958.

R. Roderick Brown is with the Massachusetts Institute of Technology, Cambridge, Mass.

This paper is taken, in part, from an S.M. thesis submitted to the Electrical Engineering Department at Massachusetts Institute of Technology. The work was conducted in the Energy Conversion Group of the Servomechanism Laboratory at the Institute, and was supported, in part, by the Wright Air Development Center under Contract *AF 33(616)3242.*

need for the improved procedure to be described is thus established.

Realization of a Nearly Ideal Procedure

The characteristics common to any realization of a nearly ideal design procedure may now be described. Clearly, the procedure must be placed upon a firm mathematical basis.

The problem of designing an optimum system may be expressed in mathematical form as the problem of minimizing a nonlinear criterion function subject to nonlinear inequality constraints (i.e., as a nonlinear programming problem). Specifically, a problem involving n_t design variables $v(=[v_1, v_2, \ldots, v_{n_t}])$ and m_t functional constraints $g_i(v)$ $[i=1, \ldots, m_t]$ may be expressed as follows: Minimize the criterion function

$$G=G(v) \tag{1}$$

subject to the following constraints:

$$\begin{array}{lll} \text{Type 1:} & g_j(v)=\alpha_j & (j=1, \ldots, m_1) \\ \text{Type 2a:} & g_k(v)\leqslant\alpha_k & (k=1, \ldots, m_{2a}) \\ \text{Type 2b:} & g_p(v)\geqslant\beta_p & (p=1, \ldots, m_{2b}) \\ \text{Type 3:} & \beta_q\leqslant g_q(v)\leqslant\alpha_q & (q=1, \ldots, m_3) \\ \text{Type 4:} & v_r\geqslant\beta_r & (r=1, \ldots, n_4) \\ \text{Type 5:} & \beta_s\leqslant v_s\leqslant\alpha_s & (s=1, \ldots, n_5) \end{array} \tag{2}$$

where

$$m_t=m_1+m_{2a}+m_{2b}+m_3 \tag{3}$$

$$n_4+n_5\leqslant n_t \tag{4}$$

and the upper bounds α and the lower bounds β are nonnegative constants. The design variables v are, of course, the physical parameters of the system and the constraints $g_i(v)$ include not only the performance specifications, but also the constraints necessary to ensure that final design be physically realizable.

It is evident that, in order to guarantee that all of the constraints be satisfied, the design procedure must consider them simultaneously. This aspect of the procedure is in direct contrast to the conventional procedure and to the method of progressive realization,[1,2] both of which consider each constraint individually. These latter methods are at best inefficient, and for many problems may be incapable of providing a solution. In addition, the minimization of the criterion function should, for the sake of efficiency, proceed concurrently with the satisfaction of the constraints. This is also in direct contrast to the aforementioned methods, wherein the minimization is considered as a distinctly separate problem.

At this point it is worth while to recognize that the design problem, in common with other minimization problems, may have several relative minima and that the minimization of the criterion function must be accomplished by employing the methods of the calculus. It will thus be impossible to determine the absolute minimum directly; it can be found only by investigating all possible relative minima. In this sense, it is impossible to realize a technique which will satisfy the first requirement of the ideal design procedure. This is not overly discouraging, however, since the number of relative minima which need be investigated will, in all probability, be small for the majority of design problems. Thus, a procedure which will determine a relative minimum will be nearly ideal and will certainly be a considerable improvement over the conventional technique.

Clearly, any technique which is formulated to solve the optimum design problem must treat the minimization of the criterion function and the satisfaction of the constraints simultaneously, employing the calculus for the former. Techniques previously developed specifically for solving nonlinear programming problems[3,4] do not meet the efficiency and versatility requirements of the ideal design procedure. However, a satisfactory procedure utilizing gradient methods may be formulated.

Design Procedure Using Gradient Techniques

Minimization of Criterion Function

Gradient methods for the minimization of an unconstrained function are well-known;[5] however, they are not directly applicable to a nonlinear programming problem. It is useful to modify the problem statement, equations 1 and 2, such that the inequality constraints are rephrased as equality constraints. This may be done by noting that a constraint of the form $F_i(v)\geqslant 0$ is equivalent to $F_i(v)=z_i^2$ (where z_i is a real variable). The variable z_i is a so-called slack variable, for it absorbs the difference, or "slack," between the value of $F_i(v)$ and 0. With the introduction of slack variables, the problem statement becomes as follows: Minimize

$$G=G(v) \tag{5}$$

subject to the equality constraints

$$f_i(v, z)=0 \quad (i=1, \ldots, m) \tag{6}$$

where

$$z=(z_1, \ldots, z_{m-m_1}) \tag{7}$$

The total number of constraints m is

$$m=m_t+m_3+n_4+2n_5 \tag{8}$$

and the total number of variables n is

$$n=n_t+m-m_1 \tag{9}$$

The classical method for minimizing a function subject to equality constraints is by Lagrangian undetermined multipliers. This method, however, requires that not m but $m+n$ simultaneous nonlinear equations be solved. Consequently, it will not be efficient, nor is it likely to be currently feasible, for the simultaneous solution of such a large number of equations is quite likely to overburden the available computing facilities.

A more feasible method utilizes the fact that the criterion function $G(v)$ is a functional (i.e., a function of functions). The constraints establish an interdependence among the variables, so that m of them are defined in terms of the remaining n-m. The m dependent variables can theoretically be expressed in terms of the n-m $(=k)$ independent variables so that $G(v)$ may in turn be expressed as an unconstrained, explicit

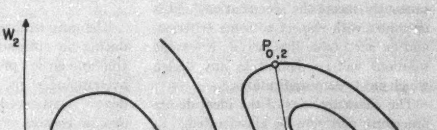

Fig. 1. Method of steepest descent in a space containing two minima

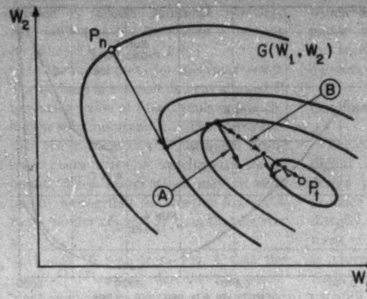

Fig. 2 (left). Optimum gradient method

A—Usual trajectory
B—Accelerated trajectory

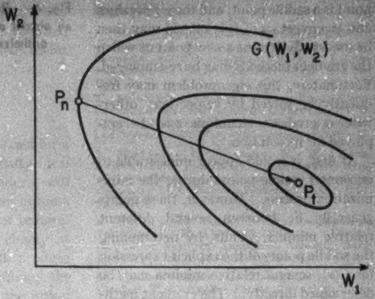

Fig. 3 (right). Newton method

function of the *k* independent variables. Although the explicit expression for $G(v)$ cannot be obtained in practice, it is possible to evaluate its gradient.[1]

The variables *v* and *z* may be considered to be the co-ordinates of an *n*-dimensional space and a particular design may be considered as a point in this space. Within the *k*-dimensional subspace of all acceptable designs there are contour lines of constant $G(v)$, which are, in general, closed lines surrounding the relative minima of $G(v)$. The gradient of the explicit expression for $G(v)$ evaluated at a point may be considered as a vector at that point which points in the direction yielding the largest possible increase in $G(v)$ per infinitesimal unit distance travelled away from the point. The negative of the gradient thus points in the direction of "steepest descent," and is always perpendicular to the contour line through the point in question. Therefore, by moving in the direction of the negative gradient, the criterion function will be decreased as much as is possible for a given infinitesimal distance moved through the subspace.

Finite steps must be taken along the gradient if the minimization is to proceed efficiently. The length of the step must, of course, be controlled so that $G(v)$ does not increase. If the latter is the only criterion used to control the length of the steps, then the gradient method for minimization being used is the familiar method of steepest descent.[6] This method is illustrated in Fig. 1 for a subspace of two dimensions, w_1 and w_2 (i.e., $k=2$). The points $P_{0,1}$ and $P_{0,2}$ are two arbitrarily selected initial points (i.e., initial designs) and $P_{t,1}$ and $P_{t,2}$ are respectively their closest relative minima. It is immediately apparent that the relative minimum which is found by the method is dependent upon the initial point selected, a feature common to all gradient methods. In addition, the method of steepest descent may be subject to time-consuming oscillations. These can be partially eliminated by utilizing the optimum gradient method,[6] wherein the length of the step is adjusted so as to achieve the largest possible decrease in $G(v)$ for the given direction. The oscillations may thus be eliminated in the region far from the relative minimum, while the accelerated optimum gradient method[7] and Newton's method[6] may be used to reduce the oscillations near the minimum; see Figs. 2 and 3, in which the contours of $G(v)$ are very nearly elliptical, indicating that P_n is near P_t.

These four different gradient methods must all be employed during the course of the minimization if the latter is to proceed efficiently. Although these methods have been described previously in the mathematical literature, no criteria for governing their application to the general problem of minimization in the presence of constraints have heretofore been developed. This paper indicates the types of criteria required, and a companion paper describes them in detail.[8]

SATISFACTION OF THE CONSTRAINTS

To evaluate the gradient of the explicit expression for $G(v)$, the *m* constraints must be satisfied at the point in question. Assuming that they are satisfied at a given point (i.e., that the point represents an acceptable design), the gradient methods indicate the proper changes to be made in the *k* independent variables. The *m* dependent variables must then also be changed so as to resatisfy the constraints. These changes will be indicated by the solution of the set of *m* nonlinear constraint equations in *m* unknowns. The most efficient method for solving this problem is the Newton-Raphson method, alternatively known as Newton's method of successive approximations.[9] The efficiency of this method arises because it can be conveniently modified to use information already determined in the computation of the gradient, and because of its potentially rapid convergence. Usually, the changes in the independent variables will be small enough so that the method will rapidly converge. Of course, an additional criterion must be placed on the size of the steps taken so as to ensure the latter. By selecting an appropriate criterion allowing a small error in the constraints, the number of iterations required by the Newton-Raphson method may be reduced to one, thus minimizing the time required to resatisfy the constraints after each change in the independent variables.

The selection of an initial point will be to some extent arbitrary, so that it is unlikely that this point represents an acceptable design. In general, several iterations of the Newton-Raphson method will be required to reduce the error in the constraints to within the allowable tolerance, providing that the method converges. Should the method be divergent, a gradient method may be used to minimize the error. Fortunately, once an acceptable design has been found for the initial point, these lengthy calculations need not be repeated, one iteration of the Newton-Raphson method being sufficient thereafter.

TERMINATION OF THE MINIMIZATION

The gradient methods will terminate at a stationary point, i.e., at a point where the gradient of the explicit expression for $G(v)$ is zero. It is usually necessary to determine if this point is a relative minimum (i.e., a solution) or a saddle point. If it is a saddle point it is necessary to employ a nongradient method to move away from the point, after which the minimization may continue as before.

The stationary point may be tested by examining a matrix which is employed in Newton's method for minimization. If the matrix is not positive definite, the point is a saddle point, and the eigenvalues and eigenvectors of this matrix may then be used to determine a new point at which the gradient methods may be re-employed. Fortunately, this eigenproblem may frequently be solved by inspection; otherwise, a gradient technique may be employed for its solution.

At first, it would appear undesirable to encounter saddle points during the minimization process. However, these points generally lie between several different relative minima. Thus, by determining the saddle points of the explicit expression for $G(v)$, several relative minima may be determined directly. The gradient methods may be constrained to converge to some of the saddle points by an appropriate selection of the initial values of the slack variables. In this fashion, the gradient methods approach the first requirement of the ideal design procedure far more closely than would otherwise be expected.

Utilization of a Digital Computer

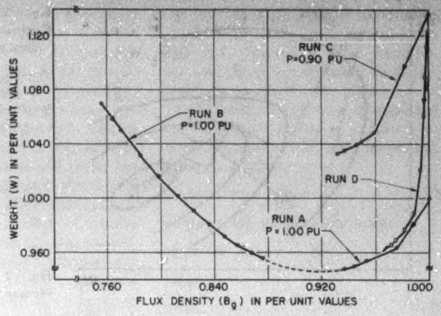
The calculations required by the gradient methods are highly complex and far more detailed than those required by the conventional design procedure. A high-speed digital computer must therefore be employed if the proposed design procedure is to be efficient and economical. The use of a digital computer is currently feasible, as evidenced by its recent application to design problems.[2,10]

At this point, it is worth while to enumerate the characteristics of the ideal computer routine. Specifically, the routine should: 1. be efficient in computer hours and in man-hours, 2. be highly generalized, and 3. require a minimum of manual intervention.

Only by meeting these requirements can the capabilities of the computer be fully exploited. The computer routines currently used by industry for the design of optimum systems are based upon the conventional design procedure and consequently fail to meet these requirements. The gradient methods, however, may be programmed for the computer so as to meet all of them.

Efficient iterative methods for performing the calculations for the gradient methods are available so that a routine requiring a minimum computer time expenditure may be written. The number of man-hours required to program the routine for any particular problem may be minimized by dividing the routine into two sections, one for the basic calculations (partial differentiation, matrix inversion, etc.) and one for the design equations $G(v)$ and the $g_i(v)$. The routine will thus be highly generalized, for it may be used to solve any design problem expressed in the form given by equations 1 and 2. Indeed, the gradient methods may be used to solve almost any nonlinear programming problem. Furthermore, the methods can produce a solution directly from an initial design by a well-defined, iterative process which can be completely automatized. Consequently, no manual intervention in the routine is required to produce a relative minimum. This is in direct contrast to the currently employed routines, wherein intervention is required after the production of each acceptable design.

Fig. 4. Results of an aircraft alternator optimization



An additional advantage in using a digital computer is the high accuracy which can be achieved. The relatively large number of significant figures which may be carried throughout the calculation coupled with reasonably accurate approximation equations will thus ensure that the fourth requirement of the ideal design procedure is met.

Example of a Design Optimization

A computer routine has been written to illustrate the applicability of the gradient methods to system optimization. For the purpose of simplification, a routine using only the method of steepest descent was coded for the Whirlwind I computer at the Massachusetts Institute of Technology. The system chosen for study was a typical 40-kva 120/208-volt 3-phase 400-cycle 6,000-rpm aircraft alternator, which was to be optimized with respect to weight W. The machine was implicitly constrained to meet these specified ratings. The total full-load, zero-power factor losses P were assumed to be the only explicit constraint $g_i(v)$ which need be considered during the optimization. The design variables chosen were the armature stack length L and the air-gap flux density B_g. All other physical parameters were held fixed.

The results of computer runs on four different problems are presented in Fig. 4. A commercial design was chosen as the base for the pu (per-unit) values of W, P L, and B_g. This design was expected to be close to the optimum. The data on each intermediate point corresponding to an acceptable design were printed by the computer in order to provide a basis for evaluating the efficiency of the method of steepest descent. Notice from Fig. 4 that B_g was found to be an independent variable. All runs were stopped when the final design differed from the optimum by no more than one per cent. This point was determined approximately, as the criterion for detecting the minimum had not been coded.

For runs A and B, the design problem was expressed as follows: Minimize the criterion function $W=G(L,B_g)$, subject to the equality constraint (type 1) $P=g(L, B_g)=1.0$.

With the commercial machine as an initial design, run A took only four steps to reach a solution. To verify this solution, run B was made from an initial design for which $B_g=0.75$ pu and L was adjusted to ensure that $P=1.0$ pu. Because this initial point was further from the solution, ten more steps were required than for run A.

For run C, the design problem was expressed as follows: Minimize $W=G(L, B_g)$ subject to the equality constraint (type 1) $P=g(L,B_g)=0.9$.

The constraint on P was not exactly satisfied at the initial point. However, the Newton-Raphson method rapidly reduced the error in P, thus indicating that small initial errors are tolerable, for they will be reduced during the optimization process.

For run D, the design problem was ex-

Vol. 7
Pt. 1
1959

pressed as follows: Minimize $W=G(L, B_g)$, subject to the inequality constraint (type 2a) $P=g(L,B_g) \leqslant 1.0$.

At the initial point for this run $P \approx 0.9$. The method of steepest descent allowed P to reach a value of 1.0 pu while approaching the solution to run A. This illustrates that the solution to this particular problem occurs when P reaches its upper bound, a conclusion which may be verified by noting that the solution for run A has a smaller value of W than that for run C.

It may be seen from Fig. 4 that the method of steepest descent was somewhat inefficient in producing a solution to run B, for which $k=m\text{-}n=1$, and particularly so for run D, for which $k=2$. The use of the other gradient methods, particularly the optimum gradient method, would have improved the efficiency greatly. However, these runs should not be evaluated on the basis of their efficiency, which should be expected to be relatively low because of the restricted use of the gradient methods. Rather, their value lies in illustrating the feasibility of using these methods for the design of optimum systems. It may be noted that while Whirlwind I required approximately 20 seconds to determine each step,[11] the use of a computer such as the International Business Machines Corporation *704* coupled with the improved calculational techniques which are described in the companion paper[8] would reduce the time required for each step of this problem to about one second.

Conclusions

The gradient methods when coded for a digital computer represent a nearly ideal design procedure. This procedure will produce one or more relative minima directly, thus satisfying the first requirement of the ideal procedure as closely as is currently possible. It will produce these solutions rapidly by utilizing the capabilities of the computer to the fullest extent, thus meeting the second requirement. The third requirement is also satisfied because the procedure is specifically designed to solve the general design problem. The fourth and fifth requirements are met by using a digital computer to perform the necessary calculations.

This paper has outlined the general philosophy of design which has led to the development of the gradient design procedure, and has described its general characteristics. In essence, the procedure consists of a complex group of criteria which have been developed to unite a number of previously known mathematical techniques. These criteria, which represent the core of the method, are described in detail in reference 8.

A Generalized Computer Procedure for the Design of Optimum Systems—Part II

R. RODERICK BROWN
ASSOCIATE MEMBER AIEE

THE general characteristics of a new and powerful procedure for the design of optimum systems have been outlined in Part I of this paper.[1] This procedure consists of a complex group of criteria specifically formulated to enable previously known gradient minimization techniques to be applied to the design problem.

This part of the paper describes in detail the criteria developed to govern the application of the gradient techniques, and concurrently presents an abbreviated discussion of the latter. In addition, the procedures required to effect a digital computer solution are described.

Preliminary Considerations

The problem of designing an optimum system may be expressed either as a nonlinear programming problem (equations 1 and 2, Part I[1]) or, by introducing the slack variables $\mathbf{z}$, as a problem in minimizing a function subject to equality constraints (equations 5 and 6, Part I). Specifically, the problem statement is: Minimize the criterion function

$$G=G(\mathbf{v}) \tag{1}$$

subject to the constraints

$$f_i(\mathbf{v}, \mathbf{z}) = 0 \quad (i=1, \ldots, m) \tag{2}$$

where

$$\mathbf{v}=(v_1, \ldots, v_{n_t})$$

$$\mathbf{z}=(z_1, \ldots, z_{m-m_1})$$

The total number of constraints m is

$$m=m_t+m_3+n_4+2n_5 \tag{3}$$

and the total number of variables n is

$$n=n_t+m-m_1 \tag{4}$$

The n variables $\mathbf{v}$ and $\mathbf{z}$ must be divided into m dependent variables $\mathbf{x}$ $(=\|x_1, \ldots, x_m\|)$ and $n\text{-}m$ $(=k)$ independent variables $\mathbf{w}$ $(=\|w_1, \ldots, w_k\|)$. It is then

This paper is taken, in part, from an S.M. thesis submitted to the Electrical Engineering Department at Massachusetts Institute of Technology. The work was conducted in the Energy Conversion Group of the Servomechanisms Laboratory at the Institute, and was supported, in part, by Wright Air Development Center under Contract *AF 33(616)3242*.

possible to evaluate the gradient of $G(\mathbf{v})$ of equation 1 by the equation[2]

$$(\nabla_f G)_i = (\mathbf{G}_w)_i - (\mathbf{G}_x)_i \|F_x\|^{-1} \|F_w\| \qquad (5)$$

where the elements of the matrices are as follows:

$\mathbf{G}_w \rightarrow \partial G/\partial w_j \quad (j=1, \ldots, k)$

$\mathbf{G}_x \rightarrow \partial G/\partial x_j \quad (j=1, \ldots, m)$

$\|F_x\| \rightarrow \partial f_i/\partial x_j \quad (i, j=1, \ldots, m)$

$\|F_w\| \rightarrow \partial f_i/\partial w_j \quad (i=1, \ldots, m;\ j=1, \ldots, k)$

provided that the determinant of the matrix $\|F_x\|$, called the Jacobian J, does not equal zero. The variables $\mathbf{x}$ and $\mathbf{w}$ may be chosen from the $\mathbf{v}$ and $\mathbf{z}$ so as to minimize the possibility that $J=0$. It is particularly important to set any slack variable z_i equal to an independent variable w_j if that variable equals zero or is likely to become zero during the solution of the problem. In addition, the restriction

$$\mathbf{G}_z \neq 0 \qquad (6)$$

must be met, so that it is recommended that as many as possible of the slack variables be termed independent variables. Thus, the design variables $\mathbf{v}$ associated with the type 4 and 5 constraints (see Part I, equation 2) will be termed dependent variables, and the necessary restriction

$$m-n=k>0 \qquad (7)$$

becomes

$$n_4+n_5<n_1-m_1 \qquad (8)$$

if these variables are to be considered explicitly during the solution. (Note that most constraints of the form $v_j \geqslant 0$ need not be considered.) The remaining variables should then be chosen so that the diagonal elements of $\|F_x\|$ are as large as possible in comparison with the off-diagonal elements, consistent with meeting the restriction imposed by equation 6. This will contribute greatly to the minimization of errors incurred during the inversion of $\|F_x\|$ by making $\|F_x\|$ as well-conditioned as possible.

Gradient Methods for Minimization

The recurrence equations

$$\mathbf{w}^{p+1} = \mathbf{w}^p + \Delta\mathbf{w}^p \qquad (9)$$

and

$$\mathbf{x}_a^{p+1} = \mathbf{x}^p + \Delta\mathbf{x}_a^p \qquad (10)$$

may be used to generate a sequence of points P_p (defined by $\mathbf{w}^p$ and $\mathbf{x}^p$) starting from some initial point P_0 and terminating at the desired minimum P_t. For the gradient methods

$$\Delta\mathbf{w}^p = -\lambda^p \|B\|^{-1} \nabla_f G^p \qquad (11)$$

and

$$\Delta\mathbf{x}_a^p = -\|F_x\|^{-1} \|F_w\| \Delta\mathbf{w}^p \qquad (12)$$

where λ^p is a positive constant used to control the distance between the points P_p and P_{p+1} (i.e., size of the vector step from P_p to P_{p+1}), $\|B\|$ is a $k \times k$ metric imposed on the space,[3] and $\nabla_f G$ is merely the transpose of $\nabla_f G$, as given by equation 5. Assuming for the moment that the constraints $f_i(\mathbf{v},\mathbf{z})$ are satisfied at P_p, it is clear that the change $\Delta\mathbf{w}^p$ will violate the $f_i(\mathbf{v},\mathbf{z})$, and the subsequent change $\Delta\mathbf{x}_a^p$ will resatisfy them only if they are linear and no roundoff or other calculational errors occurs. Since the latter cannot be expected, it is necessary to reduce this error, which can be done most readily by making the additional change in $\mathbf{x}$

$$\Delta\mathbf{x} = -\|F_x\|^{-1}\mathbf{y} \qquad (13)$$

where the elements of $\mathbf{y}$ are $y_i = f_i(\mathbf{v},\mathbf{z})$. This is equivalent to using one iteration of the familiar Newton-Raphson method. The point found employing $\Delta\mathbf{w}^p$ and $\Delta\mathbf{x}_a^p$ will be termed an approximate point $P_{p+1,a}$ and the point subsequently found from this by employing equation 13 will be termed P_{p+1}.

Generally, it is required that the percentage error in the satisfaction of the constraints be less than some small positive constant c_f. Thus each point P_{p+1} will be required to meet the restriction

$$\phi_{p+1} \leqslant c_f \qquad (14)$$

where

$$\phi \triangleq \max_i \left|\frac{y_i}{\gamma_i}\right| \qquad (15)$$

and γ_i is the bound associated with $g_i(\mathbf{v},\mathbf{z})$, i.e., either α_i and β_i. Furthermore, it is reasonable to assume that if equation 14 is satisfied at $P_{p+1,a}$, i.e., if

$$\phi_{p+1,\,a} \leqslant c_f \qquad (16)$$

then the change in $\mathbf{x}$ given by equation 13 will indeed reduce the error $\mathbf{y}$.

Four of the gradient methods for minimization of an unconstrained function may be extended to the problem at hand. These are the method of steepest descent (MSD), the optimum gradient method (OGM), the accelerated optimum gradient method[4] (AOGM), and Newton's method (NM). All methods employ the restriction

$$G^{p+1} < G^p \qquad (17)$$

in order to guarantee convergence to a minimum and, with the exception of NM, all utilize some simple metric $\|B\|$, of which the identity (or unit) matrix is probably the best for a general design problem. Aside from the restriction that equation 17 be met, the MSD is characterized by an arbitrary selection of the vector step size, i.e., of λ. In contrast, the OGM requires λ to be such that the smallest possible value of G is obtained in the direction given by $\nabla_f G$. The AOGM employs a special equation described later, and is constructed so as to prevent the OGM from settling into a time-wasting periodicity. Lastly, NM employs a special matrix of second derivatives, $\|L^*\|$ for the metric $\|B\|$ in conjunction with either the MSD or the OGM, and it can be guaranteed to converge rapidly only when $\|L^*\| \approx$ constant and is positive definite; otherwise, NM may be divergent.

Because of the possibility of predicting the value of G at P_{p+1} from that at $P_{p+1,a}$, the restriction expressed by equation 17 will be supplemented, but not supplanted, by the restriction

$$G_a^{p+1} < G^p \qquad (18)$$

Selection of a Minimization Technique

For maximum efficiency, the OGM should be employed whenever possible. In the vicinity of the minimum, the AOGM may be used to supplement the OGM, and very close to the minimum, NM may be used to advantage. In those situations wherein the OGM cannot be employed, then of necessity the MSD must be utilized.

Initially, one step in the MSD must be taken, using some arbitrary value for λ. The resultant point $P_{p+1,a}$ thus determined must be such that the restrictions given by equations 16 and 18 are satisfied. If they are not, the value of λ must be changed by multiplying it by a multiplier λ_m:

$$\lambda_m = \begin{cases} 0.5\,\dfrac{c_f}{\phi} \text{ if } \phi \geqslant c_f \\ 1 \text{ if } 0.01\,c_f \leqslant \phi < c_f \text{ and } G_a^{p+1} < G^p \\ 10 \text{ if } \phi < 0.01\,c_f \text{ and } G_a^{p+1} < G^p \\ 0.5 \text{ if } \phi < c_f \text{ and } G_a^{p+1} \geqslant G^p \end{cases} \qquad (19)$$

where ϕ and, of course, G_a^{p+1} are to be evaluated at $P_{p+1,a}$. It may be shown that this formulation for λ_m is stable and will yield a value $\lambda_m = 1$ (at which time $P_{p+1,a}$ is a tentatively acceptable point) after a reasonably short number of iterative calculations. The point P_{p+1} is then found and the restrictions expressed by equations 14 and 17 are checked. If they are not satisfied, then the prediction of the characteristics of P_{p+1} from those of $P_{p+1,a}$ was in error, so that equation 19 must be replaced by

$$\lambda_m = \begin{cases} 0.5 \text{ if } \phi > c_f \text{ or } G^{p+1} \geq G^p \\ 1 \text{ otherwise} \end{cases} \tag{20}$$

where ϕ and, of course, G^{p+1} are evaluated at P_{p+1}.

Having determined P_{p+1} by the MSD, P_{p+2} must be found either by the MSD or the OGM. If neither equation 17 nor 18 has been violated during the attempt to find P_{p+1}, then the OGM may be employed by utilizing $s\mathbf{w}^p$ and $s\Delta\mathbf{x}_a{}^p$ to find $\mathbf{w}^{p+s}$ and $\mathbf{x}_a{}^{p+s}$ $(s=2, 3, \ldots)$, equation 13 being employed after each step. In this fashion, a total of s steps is taken using the gradient evaluated at P_p, $\nabla_f G^p$. This procedure (the OGM) must be terminated as soon as equation 14, 16, 17, or 18 is violated, at which time the MSD is again employed, $\nabla_f G$ being reevaluated at the last acceptable point found. Clearly, a true OGM step has been made only if the method terminates because either equation 17 or 18 is violated.

When a termination occurs because either equation 17 or 18 is violated, it is possible to obtain a better approximation to the "optimum" point in the direction given by $\nabla_f G^p$. Let P_{p+s-1} be the last acceptable point found. Then there are three equally spaced points P_{p+s-2}, P_{p+s-1}, and $P_{p+s,a}$ available, where

$$G^{p+s-2} > G^{p+s-1} < G_a{}^{p+s}$$

The improved approximation to the optimum point, $P_{p+s,a,q}$ may be found from P_{p+s-1} by quadratically interpolating between P_{p+s-2} and $P_{p+s,a}$ thus

$$\mathbf{w}^{p+s,q} = \mathbf{w}^{p+s-1} + \lambda_q \Delta\mathbf{w}^p \tag{21}$$

$$\mathbf{x}_a{}^{p+s,q} = \mathbf{x}^{p+s-1} + \lambda_q \Delta\mathbf{x}_a{}^p \tag{22}$$

where

$$\lambda_q = \frac{G^{p+s-2} - G_a{}^{p+s}}{2(G^{p+s-2} - 2G^{p+s-1} + G_a{}^{p+s})} \tag{23}$$

These equations are directly applicable when equation 18 is violated at $P_{p+s,a}$; if equation 17 is violated at P_{p+s}, then the foregoing equations also apply after striking the subscript a from equation 23. If

$$G^{p+s,q} < G^{p+s-1} \tag{24}$$

then $P_{p+s,q}$ is the desired optimum point. If equation 24 is not satisfied, then no optimum point can be found, and P_{p+s-1} must be used as the launching point for a step in the MSD.

The distinguishing characteristic of the OGM as described herein is that the gradient $\nabla_f G$ is not evaluated at every point P_p, in contrast to the MSD, where it is. This distinction is important, since an optimum point may be found in the MSD if λ is reduced because either equation 17 or 18 is not satisfied. A point $P_{p+1,a,q}$ (or $P_{p+1,q}$) may be found from P_p in a manner similar to that described for the OGM. Given the three equally spaced points P_p, $P_{p+1,a*}$, and $P_{p+1,a**}$, where

$$G_{a*}{}^{p+1} < G^p < G_{a**}{}^{p+1}$$

the appropriate λ_q is

$$\lambda_q = \frac{G_{a**}{}^{p+1} - 4G_{a*}{}^{p+1} + 3G^p}{2(G_{a**}{}^{p+1} - 2G_{a*}{}^{p+1} + G^p)} \tag{25}$$

which is used in conjunction with equations 21 and 22 $(s=1)$.

The AOGM (accelerated OGM) may be used only when the metric $||B||$ is the unit matrix, when two or more optimum points have been found in succession, and when the current point P_p is near the minimum. Considering the three points P_a, $P_b(=P_{a+s_a,q})$, and $P_p(=P_{b+s_b,q})$ and defining

$$V \triangleq \begin{bmatrix} \mathbf{x} \\ \cdots \\ \mathbf{w} \end{bmatrix} \tag{26}$$

the AOGM utilizes the equation

$$\mathbf{V}^{p+1,a} = \mathbf{V}^p + \frac{1}{s_a + s_b}(\mathbf{V}^p - \mathbf{V}^a) \tag{27}$$

to determine the point $P_{p+1,a}$. It will be said that P_p is sufficiently close to the solution to allow the AOGM to be applied if

$$\mu < 4c_v \tag{28}$$

(μ and c_v are defined in the following section.)

The application of NM is described in the following section. It may be noted in passing that an optimum step will be taken in NM if $\lambda = 1$.

Detection of a Solution

The gradient methods will, perforce, terminate at a point where the gradient is zero, i.e., at P_t

$$\nabla_f G^t = 0 \tag{29}$$

This stationary point P_t may be either a relative minimum or a saddle point (it cannot be a relative maximum because of the restriction that equation 17 be satisfied). Now, a relative minimum is essentially a stable equilibrium point, for it is completely surrounded by regions having a higher value of G, whereas a saddle point is an unstable equilibrium point, there being regions in its vicinity which have a lower value of G. Consequently, the gradient methods (the MSD and the OGM) will generally converge to a relative minimum except when they are specifically constrained to converge to a saddle point. Since it is quite likely that there are several relative minima present in a design problem, it is clearly desirable to locate several such minima, so that the best of these may be chosen for the final optimum design. Clearly, if all such minima were located, then the best of them would be the true optimum (i.e., the absolute minimum). Since there may be several relative minima in the vicinity of a saddle point, it is thus desirable to locate saddle points.

It is known that if the functions $g_i(\mathbf{v})$ are convex (i.e., have positive second partial derivatives) for positive values of the variables $\mathbf{v}$, the solution (a minimum) will occur when all constraints are equal to their bounds,[5] i.e., when the independent slack variables $\mathbf{z}'$ are zero. Recognizing that for many design problems the $g_i(\mathbf{v})$ are not convex everywhere, it is apparent that if $\mathbf{z}'=0$ at P_t, then it is quite likely that P_t is a saddle point rather than a relative minimum. Now, if at the initial point P_0 $\mathbf{z}'=0$, then, throughout the minimization $\mathbf{z}'$ will remain equal to zero, so that these k_z variables $\mathbf{z}'$ may be eliminated from the problem (thus reducing its size) until P_t is reached, at which point they are reintroduced.

The resultant point P_t must then be tested to determine if it is a saddle point and, if so, a method for continuing the solution must be described. Consider the symmetric matrix of second partial derivatives $||L^*||$, having the elements $\partial^2 G_e/\partial w_i \partial w_j$ $(i, j=1, \ldots, k)$, where $G_e = G_e(\mathbf{w})$ is the explicit expression for $G(\mathbf{v})$ (equation 1) which could theoretically be obtained by solving the constraints (equation 2) explicitly for $\mathbf{x}$, and then substituting $\mathbf{x}$ into equation 1, thus yielding an expression in terms of $\mathbf{w}$ alone (note that $\nabla_f G \equiv$ gradient G_e). If $||L^*||$ is positive definite at P_t, then this point is a relative minimum. On the other hand, if $||L^*||^t$ is semidefinite, then P_t is a saddle point, and the appropriate directions of descent from P_t are given by the eigenvectors associated with the negative eigenvalues of $||L^*||$. For $\mathbf{z}'=0$ at P_t it is reasonably safe to say that the only negative eigenvalues of $||L^*||$ are the negative $\partial^2 G_e/\partial z'_j{}^2$, in which case the appropriate eigenvector is simply $\mathbf{e}_j$ ($\mathbf{e}_j$ is a column matrix, the only nonzero element of which is the jth element, which is unity). Thus, when $\mathbf{z}'=0$, it is necessary to examine only the $\partial^2 G_e/\partial z'_j{}^2$ at P_t. Of course, if these are all positive, P_t is a relative minimum. These partials may be calculated most readily by the numerical procedure described in the following section.

Usually it is not necessary to determine the minimum P_t exactly. An approximate solution $P_{t,a}$ is generally acceptable if it can be guaranteed to be within a certain specified distance of P_t. Manufacturing specifications commonly place a tolerance on the values of the variables $\mathbf{v}$ which can be achieved during fabrication of the system. This tolerance may be expressed as a certain percentage of the value of the $\mathbf{v}$, say, c_v. It may be expected that G will vary inappreciably over a region about P_t so that any physically realizable design determined by 1.5 c_v will be acceptable. In this case, it can be shown that if the direction of a vector step is towards P_t, an acceptable solution $P_{t,\alpha}$ will be found when

$$\mu \leqslant c_v \tag{30}$$

where

$$\mu \triangleq \max_j \left| \frac{\Delta V_j}{V_j} \right| \tag{31}$$

ΔV_j being the change in V_j determined by $\Delta \mathbf{w}^p$ and $\Delta \mathbf{x}^p$. Thus, if equation 30 is satisfied during a step in the AOGM, this method should be abandoned in favor of the MSD and, once equation 30 is again satisfied, then the MSD must be abandoned in favor of NM. Of course, if the zero-valued $\mathbf{z}'$ variables have been eliminated from the problem, then the relevant elements of $\|L^*\|$ must be eliminated, leaving a reduced matrix $\|L_{w'w'}\|$, which, by previous assumption, is positive definite, thus guaranteeing that NM would converge to P_t. Once equation 30 is satisfied in NM, $P_{t,\alpha}$ has been determined. The saddle point test described previously may be applied at $P_{t,\alpha}$, for it is assumed that $\|L^*\|^{t,\alpha} \approx \|L^*\|^t \approx \text{constant} \neq 0$. It will be recognized that the latter assumption, which is valid for a large class of system problems, is equivalent to assuming second-order behavior over a small region near the minimum.

Digital Computations

The calculations required for the gradient methods (differentiation, matrix inversion, etc.) can best be performed by numerical techniques which, fortunately, are well suited for digital computation. Indeed, if a digital computer is not employed, the time required to solve the design problem would be prohibitively great.

A finite difference equation must be employed to evaluate the first partial derivatives required for the matrices $(\mathbf{G}_z)_t$, $(\mathbf{G}_w)_t$, $\|F_x\|$, and $\|F_w\|$. The best equation which can be employed is that which requires the least computational time. (It is important to realize that it is impossible to specify which equation will give the least error.) This equation is

$$\frac{\partial f_i}{\partial v_j} \approx \frac{1}{h_j}[E_j f_i(\mathbf{v}) - f_i(\mathbf{v})]$$

$$(i=0, 1, \ldots, m;\ j=1, \ldots, n_t) \tag{32}$$

where E_j^r is a shifting operator which adds rh_j to v_j, and $f_0(\mathbf{v}) \triangleq G(\mathbf{v})$. The spacing h_j may reasonably be made:

$$h_j = \eta v_j \tag{33}$$

where η is determined by the size of the region over which the designer expects linear approximations to be valid (most probably $0.01 \leqslant \eta \leqslant 0.1$). Notice that equation 32 is not used to calculate the partial derivatives with respect to the slack variables $\mathbf{z}$. These derivatives are readily determined analytically; specifically, the only such partials which are nonzero are the

$$\frac{\partial f_i}{\partial z_i} = -2z_i \tag{34}$$

where the f_i are the type 2 through 5 constraints.

Assuming that the explicit expression for the criterion function $G_e(\mathbf{w})$ is available, the elements of the symmetric matrix $\|L^*\|$ may be calculated from

$$\frac{\partial G_e^2}{\partial w_j^2} \approx \frac{1}{h_j^2}[E_j^{-1}G_e(\mathbf{w}) - 2G_e(\mathbf{w}) + E_j G_e(\mathbf{w})]$$

$$(j=1, \ldots, k) \tag{35}$$

and

$$\frac{\partial^2 G_e}{\partial w_j \partial w_i} \equiv \frac{\partial^2 G_e}{\partial w_i \partial w_j} \approx \frac{1}{h_i h_j}[G_e(\mathbf{w}) - E_i G_e(\mathbf{w}) - E_j G_e(\mathbf{w}) + E_i E_j G_e(\mathbf{w})]$$

$$(i<j), \text{ i.e., } (i=1, \ldots, k;\ j=i+1, \ldots, k) \tag{36}$$

The expression for $G_e(\mathbf{w})$ need not be available, however, for

$$E_j^r G_e(\mathbf{w}) = E_j^r G(\mathbf{x}^*, \mathbf{w}) \tag{37}$$

where

$$\mathbf{x}^* \triangleq \mathbf{x}^p - \|F_x\|^{-1}\mathbf{y}^* \tag{38}$$

and the elements of $\mathbf{y}^*$ are

$$y_i^* \triangleq E_j^r f_i(\mathbf{x}, \mathbf{w}) \tag{39}$$

The quantity $E_i^r E_j^r G^e(\mathbf{w})$ may be evaluated similarly.

It has been tacitly assumed previously that the functions $G(\mathbf{v})$ and $g_i(\mathbf{v})$ were analytic functions of the continuous variables $\mathbf{v}$. However, when the differentiation of these functions is performed numerically, this restriction may be relaxed. In particular it is required only that the functions and the variables be continuous.

The matrix calculations may be readily carried out on a digital computer. Perhaps the most economical method for inverting a matrix is the noniterative direct-pivotal Crout method. The calculations required by equations 5, 12, and 13 may be arranged to minimize the calculational time by examining the number of multiplications required. Two basic calculational schemes may be used, the first (method A) being characterized by the immediate evaluation of the inverse of $\|F_x\|$, and the second (method B) by the evaluation of the required inverse products, such as $\|F_x\|^{-1}\|F_w\|$. The relative efficiency of these methods based on the number of multiplications involved depends upon m, k, and s (s being the number of steps taken for each evaluation of the gradient $\nabla_f G^p$). It may be shown that for $m \geqslant 6$, $s \geqslant 2$, method A is more economical on this basis. Furthermore, if $s>1$, this method may require less computer time expenditure in the transfer of information between primary (fast-access) and secondary (slow-access) memories during the operations of the Crout method, which provides additional support in favor of method A.

Errors in the evaluation of the partial derivatives and in the matrix calculations may cause the computed value of the gradient to point in the direction of increasing, rather than decreasing, $G(\mathbf{v})$. It may be said that the error in $\nabla_f G$ is not excessive as long as equation 30 is not met. Once this equation is satisfied, it is desirable to reselect the dependent variables $\mathbf{x}$ in order to ensure that the matrix $\|F_x\|$ is as well conditioned as possible. A generalized analysis of the errors propagated by the matrix operations shows that if $\|F_x\|$ is reasonably well conditioned, then these errors may be reduced further by reducing the spacing, i.e., η. However, there is no guarantee that these errors will not increase. Consequently, the irreducible error in the gradient $\nabla_f G$ will prevent accurate determination of P_t, although no difficulty should arise in the determination of $P_{t,\alpha}$.

Determination of an Initial Design

The gradient methods may be applied to the solution of the system design problem once an initial design (i.e., the point P_o) has been determined. Setting the variables $\mathbf{z}'$ equal to zero according to the previous discussion immediately fixes the values of the variables $\mathbf{v}$ which are subject to type 4 and 5 constraints. The remaining variables may then be chosen arbitrarily. Let the point so determined be P_o', which can be taken as the point P_o only if

$$\phi_0' \leqslant c_f \tag{40}$$

If equation 40 is not satisfied, then the error in the constraints must be reduced.

This may first be attempted by employing the Newton-Raphson iteration (equation 13) several times, until equation 40 is satisfied. If the iteration proves to be divergent, so that the error $\mathbf{y}$ increases rather than decreases, then a least-squares minimization must be employed; i.e., the function

$$H_f(\mathbf{v}, \mathbf{z}) = \mathbf{y}, \mathbf{y} \tag{41}$$

must be minimized. The gradient of this unconstrained function is simply

$$(\nabla H_f)_t = 2(\mathbf{y})_t \| F_x : F_w \| \tag{42}$$

so that $H_f(\mathbf{v},\mathbf{z})$ may be minimized by the techniques described herein (note that the calculations involving ϕ have no significance for an unconstrained problem). Notice that if the minimum value of $H_f(\mathbf{v},\mathbf{z})$ is sufficiently greater than zero such that equation 40 is not satisfied, then a solution to the optimization problem cannot be obtained for $\mathbf{z}'=0$ by any method without either changing c_f or some of the bounds (α or β).

Conclusions

The gradient design technique for solving system optimization problems consists primarily of a group of criteria for governing the application of gradient minimization procedures. These criteria have been selected so as to guarantee convergence to a "solution" (i.e., a relative minimum) and, as far as possible, to achieve that solution rapidly. Where necessary, they have been expressed in terms significant to the designer. A simplified version of this design technique has been coded for a digital computer[1] and the results obtained strongly indicate the need for the complete set of the procedures described herein.

These gradient methods may be applied to any problem which meets the following restrictions:

1. The criterion function $G(\mathbf{v})$ and the constraint functions $g_i(\mathbf{v})$ must be continuous functions of continuous variables.

2. The number of constraints must be less than the number of variables ($m<n$).

A valid solution can be obtained for any problem which meets the following, additional restrictions:

3. The Jacobian at a relative minimum must be nonzero ($J^t \neq 0$).

4. The second-order behavior of the explicit expression for the criterion function must dominate the higher-order behavior near a relative minimum ($\|L^*\|^t \simeq$ constant $\neq 0$).

5. The error in the evaluation of the gradient must be small.

The problem of designing an optimum system may be solved by the gradient methods if the problem meets both the foregoing and the following restrictions:

6. The optimization problem must be expressible as a problem in minimization of a function subject to constraints.

7. The system topology must remain fixed during the minimization.

(Note that restriction 7 is essentially the same as restriction 1.) The majority of system design problems can be phrased so as to meet restrictions 1, 2, 6, and 7, and in most of these cases, restrictions 3, 4, and 5 will also be met. Thus, the gradient methods may usually be employed successfully for the design of optimum systems. For further details about these methods, including a computer block diagram, see reference 6.

The Design of the Corner-Reflector Antenna

H. P. NEFF, JR.
NONMEMBER AIEE

J. D. TILLMAN
ASSOCIATE MEMBER AIEE

THE CORNER-REFLECTOR antenna has been investigated by Kraus and others.[1,2] The mathematical expressions for the array factor as given in this earlier work are cumbersome, making it difficult to design such an antenna accurately. It is the purpose of this paper to overcome this difficulty.

The method of images may be used to analyze the corner-reflector antenna for corner angles $\alpha=\pi/n$, where n is any integer other than zero. For any such corner angle the antenna and its images in the reflecting sheets form a virtual circular array of $2n$ elements with π radians of current phase shift between adjacent elements in the array. When the array factor is derived as a special case of the general circular array, much simpler mathematical expressions are obtained, making the design problem a simple one. The results of Kraus will reduce to those derived in this paper.

Derivation of the Expression for the Array Factor

A corner-reflector antenna consists of two conducting planes which intersect along some apex, and some driven radiating element, usually a dipole, located equidistant from the perfectly conducting planes. The only situation which is amenable to mathematical analysis is that in which the conducting planes are infinite in extent, and in which the angle between the planes is π/n, with n being any positive integer. Fig. 1 shows the case of $n=3$. For the case where $n=3$, the driven element and its images in the conducting sheets form a virtual circular array with $2n$ elements, and a uniform progressive phase shift between the elements of π radians.

The analysis of such a circular array is

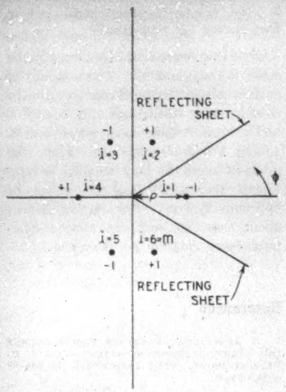

Fig. 1. The equivalence of the corner-reflector antenna array and the circular array in the plane $\theta=\pi/2$ for the case n=3

known.[3] Consider m parallel dipoles, equally spaced around the circumference of a circle of radius ρ. Let the center of the circle be located at the center of a system of spherical co-ordinates, as shown in Fig. 2. If the current in the ith element is

$$I_i=\frac{I_0}{m}\epsilon^{j\left[\omega t+\left(\frac{2\pi}{m}\right)ni\right]} \tag{1}$$

there is a uniform progressive phase shift between the elements of $2\pi/mn$ radians, and total phase shift around the ring of $2\pi n$ radians. The field from the ith element is

$$E_i=\frac{I_0}{m}\epsilon^{j\left[\omega t+\left(\frac{2\pi n}{m}\right)i+\frac{2\pi\rho}{\lambda}\sin\theta\cos\left(\phi-\frac{2\pi}{m}\right)i\right]} \tag{2}$$

The array is then found by summing E_i from 1 to m. This summation is carried out in reference 2. The result is

$$E=j^nI_0J_n(z)\epsilon^{j(\omega t+n\phi)}+I_0\sum_{k=1}^{\infty}\times$$
$$\{j^{km-n}J_{km-n}(z)\epsilon^{j}[\omega t-(km-n)\phi]+ j^{km+n}J_{km+n}(z)\epsilon^{j}[\omega t+(km+n)\phi]\} \tag{3}$$

where

$$z=\frac{2\pi\rho}{\lambda}\sin\theta.$$

For the case of the corner reflector, the number of elements in the virtual array is $2n$, so we specify that $m=2n$, which requires that m is even. The phase difference between adjacent elements is $2\pi n/m=2\pi n/2n=\pi$, which is correct for the virtual array. The array factor can now be simplified to

$$E=2I_0\epsilon^{j\omega t}\left\{j^nJ_n(z)\cos n\phi+\sum_{k=1}^{\infty}j^{n(2k+1)}J_{n(2k+1)}(z)\cos(2k+1)n\phi\right\} \tag{4}$$

as is shown in the Appendix. This expression gives the radiation pattern of the corner reflector, subject of course, to the restriction that the corner angle is π/n, and that the conducting sheets are infinite in extent.

As an example of the method, let it be required to design a corner-reflector antenna with a corner angle of 60° ($n=3$). The array factor becomes

$$E=2I_0\epsilon^{j\omega t}\{j^3J_3(z)\cos 3\phi+j^9J_9(z)\cos 9\phi+ j^{15}J_{15}(z)\cos 15\phi+\ldots\ldots\} \tag{5}$$

In the plane of the array

$\theta=\pi/2$, and

$$z=\frac{2\pi\rho}{\lambda}.$$

For a one-lobed pattern then the designer must choose a radius, ρ, or antenna-to-apex spacing such that $J_9(z)$, $J_{15}(z)$, etc.

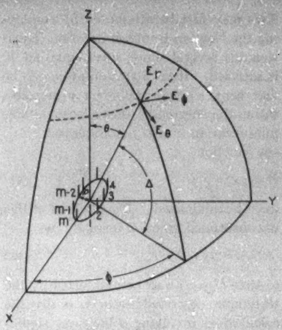

Fig. 2. Co-ordinate system used for analysis of ring arrays

are negligible compared to $J_3(z)$. This condition is usually satisfied if $z\leqq n$ due to the rapid decrease in magnitude of the higher order Bessel functions. For the example above

$$\frac{2\pi\rho}{\lambda}=3$$

$$\frac{\rho}{\lambda}=\frac{3}{2\pi}=0.477$$

$$J_3(3)=0.30906$$

$$J_9(3)=0.00008$$

$$J_{15}(3)=2.9\times10^{-9}$$

All terms except the first in equation 5 may be neglected leaving $E=k\cos 3\phi$ where k is a constant.

In order to obtain an array factor with a maximum magnitude in the direction $\phi=0$, $\theta=\pi/2$, it is necessary to require that

$$\rho\leqq 0.699\lambda \text{ or } z\leqq 4.2\ (n=3),$$

since $J_3(z)$ is maximum for this value of z. As the value of ρ is decreased below

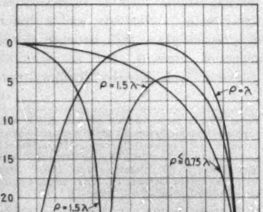

Fig. 3 (left). Array factor for corner angle of 60°, ($n=3$), in the plane $\theta=\pi/2$

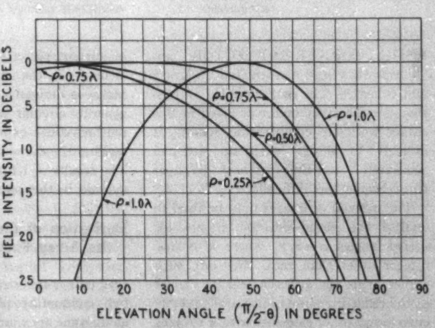
Fig. 4 (right). Array factor for corner angle of 60°, ($n=3$), in the plane $\phi=0$



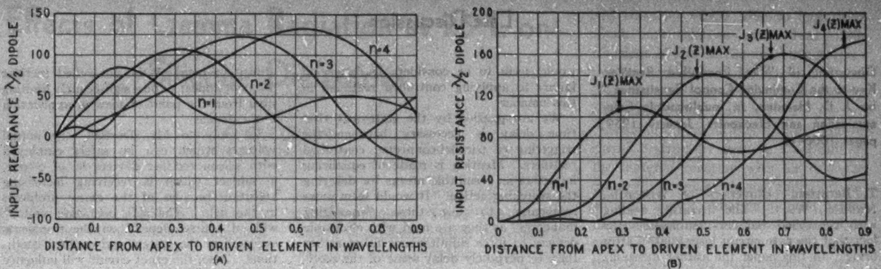


Fig. 5. **Input resistance and reactance in ohms with λ/2 dipole as the driven element**

A—Resistance B—Reactance

the value given in the preceding statement, the shape of the array factor remains substantially the same. The magnitude of the array factor decreases approximately as $J_3(z)$ with z decreasing. If the driven element of the corner reflector is a half-wave dipole at $\rho=0.669\lambda$, then its input resistance will decrease as ρ decreases. With constant input power to the antenna terminals it should be possible to maintain approximately constant field strength in the direction $\phi=0$, $\theta=\pi/2$. In this manner the corner-reflector antenna may be a broad-band antenna. The array factor as a function of antenna-to-apex spacing is shown in Fig. 3 and Fig. 4 for the cases $\theta=\pi/2$ and $\phi=0$, respectively.

Thus, for any corner-reflector antenna with corner angle π/n the array factor becomes

$$E=KJ_n\left(\frac{2\pi\rho}{\lambda}\sin\theta\right)\cos n\phi+\text{residual terms}$$

The designer must merely choose a radius such that the residual terms may be neglected. This is the expression for the pattern of an array of isotropic radiators, and must be multiplied by the expression for the pattern of the driven element to obtain the equation of the final pattern. Obviously, no radiated field will exist outside the corner angle under the original assumptions.

The input impedance of the driven element may be calculated very simply due to the symmetry of the array. In general, as shown by Kraus,[1,2]

$$Z_{in}=Z_{11}+\sum_{i=1}^{n}\epsilon_i\cos\pi iZ_{1\,i+1} \qquad (6)$$

where $\epsilon_i=1$ when $i=n$, and $\epsilon_i=2$ otherwise. For the case above ($n=3$).

$$Z_{in}=Z_{11}-2Z_{12}+2Z_{13}-Z_{14}$$

Results are shown in Fig. 5 for a half-wave dipole as the driven element.

Conclusions

The results given here for the corner-reflector antenna relate the pattern to the spacing from the apex to the driven element in a much clearer manner than the previous analyses. A satisfactory design can be obtained by choosing this spacing so as to minimize the residual terms. Maximum field for a given size current occurs if this spacing is chosen to maximize the factor $Jn(2\pi\rho/\lambda\sin\theta)$.

Appendix

Derivation of Expression for Array Factor

Equation 3 gives the array factor of a circular array of m element, with a progressive phase difference of $2\pi/mn$ between adjacent elements. For the virtual array formed by a corner reflector $m=2n$, and equation 3 becomes

$$E=j^nI_oJ_n(z)\epsilon^{j(\omega t+n\phi)}+ I_o\sum_{k=1}^{\infty}\left\{j^{(2k-1)n}J_{(2k-1)}(z)\epsilon^{j[\omega t-(2k-1)n\phi]}+ j^{(2k+1)n}J_{(2k+1)n}(z)\epsilon^{j[\omega t+(2k+1)n\phi]}\right\} \qquad (7)$$

The first term of the summation is $I_oj^nJ_n(z)\epsilon^{j(\omega t-n\phi)}$, and this can be combined with the leading term to give

$$2j^nI_oJ_n(z)\cos n\phi\epsilon^{j\omega t}$$

In the same way the second term of the summation is

$$j^{3n}I_oJ_{3n}(z)\epsilon^{j(\omega t+3n\phi)}$$

resulting from $k=1$, and the third term, coming from $k=2$ is

$$j^{3n}I_oJ_3{}^n(z)\epsilon^{j(\omega t-3n\phi)}$$

These combine to give

$$j^{3n}I_oJ_{3n}(z)\cos 3n\phi\epsilon^{j\omega t}$$

Then equation 7 can be written

$$E=2I_o\epsilon^{j\omega t}\left[j^nJ_n(z)\cos n\phi+ \sum_{k=1}^{\infty}\epsilon j^{(2k+1)}J_{(2k+1)}(z)\cos(2k+1)n\phi\right] \qquad (8)$$

This is equation 4 of the text.

Late Discussion

Discussion of "The Controlled Rectifier: Key to the Continuing Control Renaissance," by J. D. Harnden, Jr., published in Communication and Electronics, January 1959, pages 1006–12.

T. Bernstein (University of Wisconsin, Madison, Wis.): The literature dealing with controlled rectifiers emphasizes the fact that the gate circuit loses control after firing. In this paper the author mentions that there is a possibility that the controlled rectifier can be turned off by gate action. Have such units been made as yet? What would be the magnitude of the gate signal necessary to turn off the rectifier as compared to the signal necessary to turn it on? Since the controlled rectifiers presently available are not designed for reverse voltage on the gate junction, I am in doubt as to whether the turn-off gate voltage would be a reversed polarity gate signal. This information will be useful as an indication of the future potentialities of the controlled rectifier.

I. K. Dortort (I-T-E Circuit Breaker Company, Philadelphia, Pa.): In arriving at some estimate of the efficiency of equipments using the controlled rectifier *ZJ-39A*, the author points out that the forward drop is but one volt out of a peak voltage rating of 400. We assume the peak voltage rating is equivalent to the PIV (peak inverse voltage) rating of power diodes, in which case it is expected that the recommended rms alternating voltage to be applied to these rectifiers would not be much over 115 volts. Even at this reduced voltage, the efficiency is still excellent. However, the author's statement raises the question of recommended peak operating voltage. This question is further emphasized by the statement that it is possible to use these devices in a control system in which forward conduction is initiated by exceeding the breakover voltage instead of a signal on the control electrode. Since the forward breakover voltage and the PIV rating of the rectifier are stated to be approximately equal, there would seem to be considerable danger of failure in applying controlled rectifiers in this manner.

We are puzzled by the statement that time delay is necessary between the triggering of parallel-connected controlled rectifiers. Mention is made of equalizing inductors as a suitable means for delaying the switching action. It would seem more reasonable to use these "equalizing inductors" as they are used with electronic devices to force simultaneous firing rather than to purposely delay some of the rectifiers and thereby cause them to carry less than their proportionate share of load.

The bridge-connected rectifier of Fig. 2(H) is claimed to have inherent commutation protection. I do not understand what is mean there: Would the author explain?

J. D. Harnden, Jr.: In reply to Mr. Bernstein, at present, the controlled rectifier is primarily intended for operation in circuits in which turn-off is accomplished by commutation. This implies that the device is not intended to be operated in a turn-off direction by gate action. With the present production *C35* device it is possible to turn off anode-cathode current flow by diverting a portion of the current out through the gate circuit. However, this action is only possible in the relatively low-current region such as 500 milliamperes or less. Under such operation, the current flow in the gate lead is considerably greater than required to initiate conduction through the controlled rectifier. In evaluating the merits of a device which can both turn on and turn off a circuit, it becomes necessary to consider not only resistive but reactive loads.

It is, of course, necessary to consider the transient energy involved in opening a reactive circuit. Some provision must be made to protect the semiconducting device, in addition to absorbing its energy. Generally speaking, this involves the use of additional energy absorbing or protecting equipment. In most instances, it appears that this requirement is no less stringent than that involved in the commutation of a thyratron-like device. Therefore, the ability to turn off the controlled rectifier does not appear to be a significantly limiting item from the point of view of application of the device.

In reply to Mr. Dortort, the actual voltages which can be safely employed with silicon rectifier devices is, of course, a subject which is receiving increasing attention because of the many problems in the field. The safe operating voltage will, of course, depend on the transients expected in the system and on load conditions. Also, the exact circuit will influence the safe voltage for operating the devices.

The statement with regard to turning on the controlled rectifier by breakover voltage instead of a signal on the control electrode or gate implies, of course, that adequate protection methods will be used, so that the peak inverse rating of the device is not exceeded. This may take the form of an auxiliary series rectifier so as to extend the PIV rating. However, in general, this method of application will be used with unidirectional pulses so there is no danger with respect to the reverse voltage.

The statement concerning turn-on of parallel-connected devices is based primarily on the fact that there is a finite and measureable turn-on of the controlled rectifiers in addition to a measurable and finite delay time. Therefore, since these times are widely different in controlled rectifiers, it may be possible for one unit to be turned on sufficiently to prevent the other controlled rectifier from turning on. This means that the first unit to be completely turned on may act as a clamp or switch with regard to the other units in the system. The reference does not imply that there is any difference in the application of the gate pulse to all of the units which may be operating in parallel. Generally, however, it appears that the leads normally employed in connecting the controlled rectifiers possess sufficient inductance so that the turning-on action is almost inherently equalized.

The reference to commutation protection of the bridge rectifier circuit refers to operation with inductive loads, etc., wherein the normal diodes provide a free-wheeling path, thus protecting the controlled rectifiers from transient disturbances.

Effects of Gamma Radiation at 25 C on Silicone Dielectrics

C. G. CURRIN
ASSOCIATE MEMBER AIEE

ELECTRIC EQUIPMENT such as pump motors, instrumentation, control apparatus, and wire and cable, is necessary for the operation of nuclear reactors in central stations and in marine, rail, and aeronautical transportation equipment. For engineering and economic reasons, some of the electric apparatus is placed close to the reactor in regions of strong nuclear radiation. So that equipment can be designed to be reliable when exposed to this radiation, engineers require data on the behavior of all the components and materials when subjected to this environment.

To obtain radiation-effects data on one group of dielectrics, measurements of effects of gamma radiation on physical and dielectric properties of liquid, semisolid, elastomeric, and resinous silicones are being made. These measurements indicate that many silicone dielectrics have appreciable resistance to radiation exposure.

Basic Radiation Effects

The radiation exposure to which electric apparatus is subjected varies with the energy rating of the reactor, the shielding between the reactor and the apparatus, the geometry of the reactor and equipment, and the expected life of the apparatus in terms of reactor operating time. Such exposures may vary from 10 to 10,000 megarads.[1]

Nuclear radiation affects some types of materials much more than other types. Certain solid-state devices, such as transistors and rectifiers, are damaged severely by relatively small radiation exposures. Other crystalline materials such as iron, copper, and mica are many times more resistant. Organic or polymeric materials, used primarily as electrical insulation in electrical equipment, are intermediate in resistance to radiation. The radiation exposure necessary to damage insulating materials varies considerably since it is dependent upon the composition, type, and application of the insulation.

The primary mechanisms by which radiation affects polymeric materials have been shown to involve ionization and excitation.[2,3] This is true for each of the major types of radiation, beta, gamma, and neutron, found near nuclear reactors. The degree of ionization or excitation is proportional to the total radiation energy absorbed by the material. The fundamental unit for absorbed radiation energy is the rad (1.0 rad = 100 ergs absorbed/gram material). A more convenient unit for describing effects on dielectric materials is megarad (rads$\times 10^{-6}$). The AIEE Subcommittee on Effects of Radiation on Insulation has adopted the rad and megarad as standard units of irradiation dose for reporting radiation effects. Radiation doses required to affect polymeric materials are usually from 1.0 to 1,000 megarads.

Ionization and/or excitation results when chemical bonds in polymeric materials are broken by absorbed radiation energy. The resulting ionic species usually recombine forming new and often different chemical bonds. The structure of the polymer is thereby altered, changing the physical properties of the material. Depending upon the manner in which the chemical bonds are broken and reformed, the material becomes either brittle or soft.

Changes in the chemical structure of a polymer also modify the dielectric properties. Furthermore, minute traces of radiation-induced impurities have a sizeable effect on these properties. Some of these impurities are ionized atoms, others are electrons freed by the radiation from the parent atoms. Still other impurities are ionized fragments of the original polymer or new stable compounds.

Excluding the stable compounds, these impurities have a limited life before combining with one another or with the material. Therefore the effects of radiation on dielectric properties are of two types: permanent effects, due to the stable impurity compounds and rearrangement of the chemical structure, and transient effects, due to impurities which have relatively short lives. The transient effects on the dielectric properties are dominant during irradiation and also, for some materials, immediately after irradiation.[4]

Some of the impurities or alterations in chemical structure may be the result of the material reacting with air or some other environment during radiation exposure. Hence radiation-induced oxidation or other similar chemical reactions may be the cause of some of the radiation effects. This environmental factor is analogous to effects of high temperature on the stability of polymeric materials.

The temperature of the polymeric material during radiation exposure influences the mobility of the ionized impurities and thus affects the rate at which radiation effects are produced. The intensity of radiation has also been shown to be a factor in at least one material, as discussed in an unpublished paper by Jerome Goodman and J. H. Coleman.

The amount of high-energy beta or gamma radiation absorbed by a polymeric material, which determines the degree of ionization, is primarily a function of the density. In a neutron field, however, the energy absorbed is largely determined by the atomic composition of the material. Polymeric materials are usually composed of hydrogen, carbon, oxygen, and in some cases nitrogen and silicon atoms. All of these atoms have relatively small neutron absorption coefficients, yet those polymeric materials containing boron, lithium, or similar additives with high neutron absorption coefficients, may be expected to absorb much more energy from a neutron field.[5]

Silicone Insulation Evaluation Program

A continuing program was initiated to measure the major effects of radiation on the physical and dielectric properties of a number of typical silicone insulating materials. Silicones are noted for reliability and performance in severe temperature and moisture environments; this program is to evaluate these dielectrics under a third environmental condition, nuclear radiation.

This test program involves only silicone materials and simple combinations of these dielectrics with certain inorganic materials. Since the immediate environment of a material may be a major factor in determining the radiation resistance of a material, a separate program is necessary to evaluate the resistance

Paper 59-117, recommended by the AIEE Electrical Insulation Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted November 10, 1958; made available for printing January 13, 1959.

C. G. Currin is with the Dow Corning Corporation, Midland, Mich.

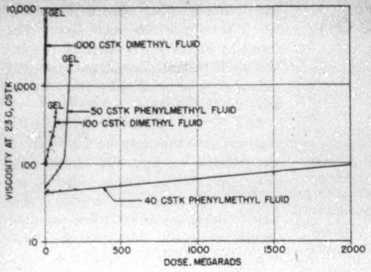

Fig. 1 (left). Viscosity of irradiated silicone fluids

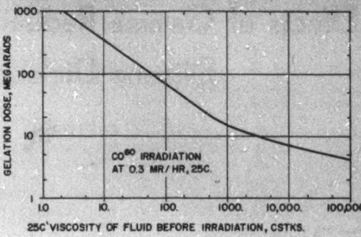
Fig. 2 (right). Radiation dose required to gel linear dimethyl silicone fluids



of silicone insulation systems. Four types of silicone dielectrics are studied: liquids, compounds, elastomers, and resins.

Samples of these materials are exposed to cobalt 60 gamma radiation. Cobalt 60 emits rays of 1.17 and 1.33 million electron volt (Mev) energies. The environment around the multikilocurie hollow cylindrical source used is air at atmospheric pressure and room temperature.

Samples of silicone liquids are placed in 4-ounce glass bottles; the bottles are vented by a small hole in each cap to allow the escape of gases evolved from the liquids during irradiation. The samples of compounds are placed in 2-ounce tin ointment cans; samples of elastomers and solids are either without a protective container or are wrapped in 0.006-inch thick aluminum foil. However, no significant evidence has been found that any of these container materials affects the radiation damage mechanism.

To determine the irradiation dose received by the samples, calculations are made on the basis that the samples absorb the same energy from the radiation field as water would which is the normal technique for polymeric materials.[6]

The dose rate, or rate of energy absorption, is determined by the strength and configuration of the source and the distances between the source and the sample. Dose rates from 0.02 to 0.7 megarads/hour (per hour) are obtained based on ferrous sulfate dosimetry. However, for most of the exposures, the dose rate is between 0.3 and 0.7 megarads/hour.

The spatial distribution of the radiation intensity and the size and orientation of the sample largely determine the consistency of the irradiation dose over the volume of the sample. For this reason, only thin samples are placed in regions of substantial radiation-intensity gradient. The maximum difference in dose between two regions of any sample does not exceed 25%.

Basic physical and dielectric properties of the samples are measured after the radiation exposures. An exponential decay of certain properties with time after exposure have been reported for some materials.[4] The time constants of the decays observed with silicone insulation have been less than 10 minutes; thus the properties are essentially stable one hour after irradiation. Even so, measurements are usually not made until at least 24 hours after the radiation exposure.

The physical properties measured vary with the physical form of the materials. In general, however, obvious changes in appearance are recorded and a measurement of the hardness of a solid or viscosity of a liquid is made. Hardness or viscosity is one indication of alteration in chemical structure by the irradiation.

Four major dielectric properties of the irradiated samples are measured. Electric strength, volume resistivity, dielectric constant, and dissipation factor are measured at 23 C (degrees centigrade) or 25 C. Arc resistance of some of the irradiated samples is also measured.

The four major dielectric properties of several representative materials are also measured during exposure to gamma radiation. Dose rates from 0.02 to 0.5 megarads/hour are employed in these tests. Special techniques are used to make the resistivity and complex permittivity measurements, since air surrounding the sample is highly ionized by the radiation.

It was found necessary to submerge the samples and the guarded electrode system, including the cable connections, in a dimethyl silicone liquid dielectric to minimize effects of the ionized air. Although the silicone liquid is also ionized, the dielectric losses are much less than those of the ionized air.

Descriptions of the test methods, equipment, and samples are detailed in the Appendix.

The data being obtained during the evaluation program are statistically analyzed when practical to obtain the best estimate of the radiation effects and the statistical confidence limits thereof. Confidence limits at the 95% level are used; that is, there was no more than a 5% probability that each significant conclusion was made in error.

Radiation Effects on Liquids

The effects of gamma radiation on silicone fluids are demonstrated by data on four different Dow Corning Corporation fluids:

Silicone Fluids	Centistokes(Cs)
A—Dimethyl, 200	100
B—Dimethyl, 200	1,000
C—Phenylmethyl, 510	50
D—Phenylmethyl, 704	40

The first two are typical silicone fluids used as liquid dielectrics in capacitors and liquid immersed equipment. They differ primarily in viscosities.[7] The 50-cs phenylmethyl silicone fluid contains only a small number of phenyl groups. The 40-cs phenylmethyl silicone fluid is a low-molecular-weight polysiloxane with approximately equal numbers of phenyl and methyl groups.

PHYSICAL PROPERTIES

Fig. 1 shows that exposure to gamma radiation increases the viscosities of all these liquids indicating an increase in molecular weights. The figure shows that the increase, in general, follows the equation

$$\log\left(\frac{\nu}{\nu_0}\right)=\beta_\nu D \qquad (1)$$

when ν is the viscosity after irradiation, ν_0 is the viscosity prior to radiation exposure, β_ν is the coefficient of viscosity increase, and D is the irradiation dose. As the dose absorbed by silicone fluids increases beyond a critical value, the rate of increase of viscosity is sometimes greater than that indicated by equation 1. After a dose approximately 50% greater than this critical dose, the fluid gels and becomes a soft rubbery solid.

Fig. 1 also shows that the rate of viscosity increase is markedly different among these four liquids. This rate of viscosity increase, β, in equation 1, is tabulated for the four fluids.

Silicone Fluid, Cs	Approximate Phenyl/Methyl Ratio	β_v, Megarad^{-1}
100, dimethyl	0.00	0.0079 ±0.0013
1,000, dimethyl	0.00	0.063 ±0.032
50, phenylmethyl	<0.1	0.0026 ±0.0001
40, phenylmethyl	1.00	0.00017 ±0.00002

Dimethyl silicone fluids with high viscosities are the least resistant to radiation effects on viscosity. Also, the radiation resistance increases with an increasing proportion of phenyl to methyl groups in the fluid.

After a dose usually greater than that required to double the viscosity, the fluid will gel. The irradiation dose required to gel dimethyl silicone fluids has been found in the following manner.

It has been shown that the dose required to gel a liquid is

$$D_{gel}=\frac{481.6\times10^{3}}{G\ Mw}\ \text{megarads} \qquad (2)$$

when G is the number of chemical bonds created by 100 electron volts of irradiation energy and Mw is the average molecular weight.[8]

Experiments were made to determine the dose required to gel linear dimethyl silicone fluids of 100- and 1,000-cs viscosity. It was found that at a dose rate of 0.3 megarad/hour and exposure at 25 C, on an average 65±5 megarads would gel 100-cs fluid and 14.0±2.0 would gel 1,000-cs fluid. Obtaining the molecular weights of these fluids by two separate methods, equation 2 can be used to estimate the value of G for linear dimethyl silicone fluids. The calculations are tabulated in Table I.

Substituting the best estimate of G for these linear dimethyl silicone fluids, and assuming that G does not vary appreciably with molecular weight, equation 2 may be reduced to

$$D_{gel}=\frac{423\times10^{3}}{Mw}\ \text{megarads} \qquad (3)$$

Calculated gelation doses for dimethyl silicone fluids having room temperature viscosities from 2.0 cs to 100,000 cs are plotted in Fig. 2. The gelation doses for fluids of this viscosity range vary from 1,100 megarads for the 2.0-cs fluid to 4.0 megarads for the 100,000-cs fluid.

Table I. Calculations for Value of G

Dimethyl Silicone Fluid Viscosity, Cs	D_{gel}, Megarads	Mw, Avg.	G, Bonds Formed per 100 Electron Volts
1,000	14	32,500*	0.98
	14	26,400†	1.30
100	65	6,500*	1.14
	65	6,600†	1.12
		Average	1.14±0.21

* For authority for *Mw* quantities, see ref. 9.

† For authority for *Mw* quantities, see ref. 10.

This value of G is for gelling only dimethyl silicone fluids. Sufficient data on the gelation of phenylmethyl silicone fluids are not available; hence, the G value for most of these liquids can not be calculated. However, since the presence of phenyl groups greatly increases the resistance of silicone fluids to viscosity changes and gelation, the G value of these fluids is expected to be much less.

Other physical properties of silicone fluids are also affected by radiation exposure. The densities increase slightly and are proportional to the increases in viscosity. However, these increases are slight and are of little engineering significance. In the case of the 50-cs phenylmethyl silicone fluid, the density increases by 1.0% after 140 megarads of irradiation, the dose required to double the viscosity. There is also a similar small increase in the refractive index.

The color of the dimethyl silicone fluids remains water-white during irradiation, even after gelation takes place. The color of the phenylmethyl silicone fluids becomes amber upon irradiation and darkens after heating the fluid to 250 C for 4 hours.

Of major engineering importance, however, are the gases evolved from silicone liquids during irradiation. Although no measurements of the quantity or composition of the gases which evolve have been made in this study, previously published data indicate that three different gases are produced:

Component Gas	Quantity, Volume Per Cent
Hydrogen	34.4
Methane	61.0
Ethane	4.6

These are mass-spectrometer data of the gases evolved from a dimethyl silicone fluid irradiated 50 megarads by a cobalt 60 gamma radiation source.[11]

Considering the chemical structure of the silicone fluids and of these simple gases, probably the same mechanism which increases the viscosity also produces these gases; this mechanism is known as cross-linking.

Considering the cross-linking mechanisms probable, the number of molecules of gas produced, regardless of the composition, is approximately equal to the number of cross-links formed in the polymer by irradiation. However, this approximation may be in error by a factor or two or slightly more.

This approximation can be used to obtain an estimate of the quantity of gas evolved. The number of cross-links formed by the gelation dose can be derived from the G value previously calculated. Remembering that this is an average value of G over the total dose required to gel the fluid, it can be shown that 1 megarad of irradiation will produce $6.3\times10^{17}\,G$ crosslinks in a silicone liquid.

Using the gelation value of G for dimethyl fluids, 1.14, calculations show that 0.03 milliliter of gas at 0 C and 760 millimeters pressure are evolved from one gram of fluid by a dose of one megarad. Considering the range of approximation made, the quantity of gas evolved by 1 megarad can be estimated to be between 0.01 and 0.05 milliliter per gram of fluid. Since the value of G does not vary appreciably with the different viscosity grades of these fluids, all dimethyl fluids can be expected to have the same gas evolution rate.

This estimate of gas evolution indicates that an exposure of 50 megarads will produce gas with a volume approximately 150% of the parent dimethyl fluid. The phenylmethyl silicones, which have much smaller values of G, produce substantially less gas.

In sealed equipment, such as silicone impregnated capacitors, this gassing may be the major detrimental effect of radiation exposure. To insure reliability, such components or equipment must be provided with a safe method for venting the gas.

DIELECTRIC PROPERTIES

There are two basic types of effects of irradiation on the dielectric properties: the permanent effects observed after irradiation and the transient effects found during and sometimes immediately after the radiation exposure. These two types of effects were studied separately.

Permanent Effects. Irradiation causes a small increase in the dielectric constants of silicone fluids. This increase at frequencies of 100 cps (cycles per second) and 0.1 mc/sec (megacycles per second) is shown in Fig. 3(A) for two types of fluids. The effects on the 1,000-cs dimethyl fluid are similar to those shown for the 100-cs dimethyl fluid. The increase indicates the formation of polar groups, since cross-linking of silicone fluids has no appreciable effect on the dielectric constant.

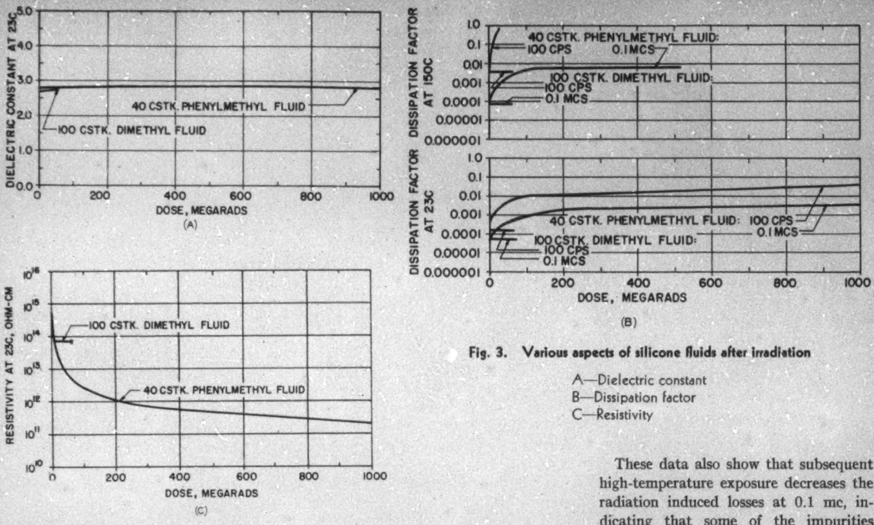


Fig. 3. Various aspects of silicone fluids after irradiation

A—Dielectric constant
B—Dissipation factor
C—Resistivity

The increase in the room temperature dielectric constants of silicone fluids is proportional to the dose. Thus, the dielectric constant can be mathematically related to the dose by the equation

$$K = K_0 + \beta_k D \tag{4}$$

when K is the dielectric constant of the irradiated fluid, K_0 is the dielectric constant prior to irradiation, β_k is the coefficient of increase in dielectric constant, and D is the dose. Values of β_k for the 25 C 0.1-mc dielectric constant for three silicone fluids are tabulated in the following:

Silicone Fluid, Cs	β_k, Megarads^{-1}
100, dimethyl	0.006 ±0.0004
50, phenylmethyl	0.00043±0.00008
40, phenylmethyl	0.00012±0.00003

Again the phenylmethyl silicone fluids are more resistant to radiation effects.

As expected, the dielectric constants at 150 C are lower, approximately 2.4, and are less affected by radiation exposure.

There is a major difference between irradiated dimethyl and phenylmethyl silicone fluids, however, when the dissipation factor is considered. Fig. 3(B) shows radiation exposure has no appreciable effect on the dissipation factor of a dimethyl silicone fluid at frequencies from from 50 cps to 0.1 mc at either 23 C or 150 C.

However, as further shown in this figure, radiation exposure has a drastic effect on phenylmethyl silicone fluids. These fluids, which are otherwise the least affected by radiation, have relatively little resistance to effects on the dissipation factor.

The rate at which the dissipation factor of phenylmethyl fluids is affected decreases exponentially with increasing dose. This is unique. For almost all properties which have been measured on any material, the radiation effects are primarily a linear function of the dose. The exponential decrease indicates the mechanism by which the dissipation factor is affected is different from that which increases the viscosity; i.e., cross-linking. Since the rate decreases exponentially, this mechanism must be affected by the products of the process.

It is believed that the increase in dissipation factor is due to radiation damage to the phenyl group in phenylmethyl silicone fluids. This damage results in stable impurities, some of which are not volatile even at 225 C. This stability is indicated by the following data for the 40-cs phenylmethyl fluid after a dose of 100 megarads.

Test No.	Dissipation Factor at 23 C			
	Before Heating		After 4 Hours/250 C	
	100 Cps	0.1 Mc	100 Cps	0.1 Mc
1	0.0078	0.0026	0.033	0.00042
2	0.0079	0.0026	0.035	0.00042

These data also show that subsequent high-temperature exposure decreases the radiation induced losses at 0.1 mc, indicating that some of the impurities formed are either volatile or not thermally stable. The impurities formed by irradiation are not in sufficient quantity for detection by normal infrared analytical techniques.

Radiation exposure has a similar effect on the resistivity of silicone liquids, as is shown in Fig. 3(C) for one dimethyl silicone fluid and one phenylmethyl fluid. Radiation causes a small but statistically significant increase in the resistivity of dimethyl silicone fluid. Irradiation has a much greater effect on the phenylmethyl fluids; the rate of this is exponential. This indicates that the mechanism for this decrease in resistivity is probably the same as that causing the increase in dissipation factor.

The d-c electric strength of the fluid is damaged by exposure to gamma radiation. This damage occurs in both dimethyl and phenylmethyl fluids and is shown in Fig. 4 for the 40-cs

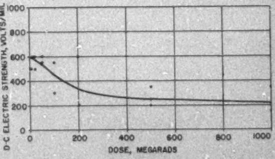

Fig. 4. Electric strength of 40-cs phenylmethyl fluid after irradiation; 0.020-inch gap between 0.50-inch-diameter spherical electrodes

Vol.
Pt. I
195

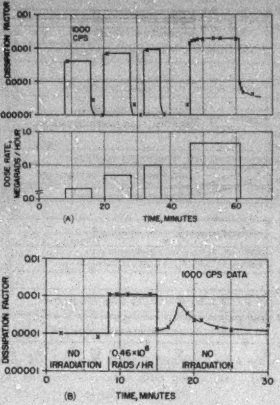

Fig. 5. Dissipation factor of silicone fluids during and after irradiation

A—100-cs dimethyl

B—50-cs phenylmethyl

phenylmethyl fluid. Irradiation reduces the average d-c electric strength to approximately one half of that of nonirradiated silicone fluids.

After irradiation the variations of the individual breakdown voltages increase. With the test equipment used, the coefficient of variation for nonirradiated fluids is less than 5%. The coefficient for the 40-cs phenylmethyl fluid data irradiated from 100 to 1,000 megarads is 45%; this difference is statistically significant at a high level. Thus, the practical electric strength of irradiated silicone fluids is considerably less than that indicated in Fig. 4. Results from the a-c measurements are similar to the d-c electric strength data.

Transient Effects. The intensity of radiation is the major factor in determining dissipation factor and resistivity during radiation exposure. Those effects which exist are transitory in nature and disappear immediately or shortly thereafter when the exposure is stopped.

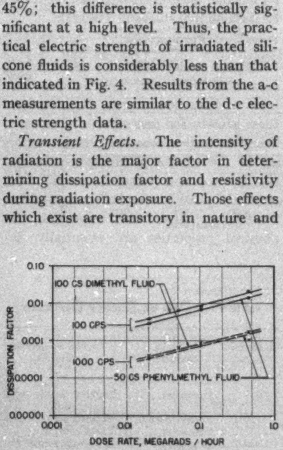

Fig. 6. Dissipation factor of two silicone fluids during irradiation

No significant transistory effect of irradiation was found on the dielectric constant of the 100-cs dimethyl fluid or the 50-cs phenylmethyl fluid.

The dissipation factor is grossly affected by the radiation exposure, however, as shown in Fig. 5(A) for the 100-cs dimethyl fluid and in Fig. 5(B) for the 50-cs phenylmethyl fluid. At dose rates greater than 0.1 megarad/hour, the 1,000-cps dissipation factor is a decade or two greater than prior to the irradiation. These figures also show an effect of time on the dissipation factor of both fluids although it is much more pronounced with the phenylmethyl fluid immediately after the irradiation ceases. In both fluids the time effect disappears within 15 minutes.

Measurements made after 16 hours of continuous irradiation did not indicate any time effects not evident during the first few minutes of irradiation.

At 100 cps, the dissipation factor during irradiation is even greater than at 1,000 cps as shown in Fig. 6. These data also indicate a linear relationship between the logarithm of dissipation factor and the logarithm of dose rate; the coefficient of this relationship is 0.50 for both types of silicone fluid measured at 100 and 1,000 cps.

A similar effect on resistivity is shown in Fig. 7 for the 100-cs dimethyl fluid. Data obtained on the 50-cs phenylmethyl fluid fall essentially on the same line. Here, however, the coefficient of the logarithm of resistivity-logarithm of dose-rate relationship is between 0.50 and 0.73.

Three measurements were made of the d-c electric strength of each type of silicone fluid during irradiation. The average breakdown voltage between 0.50-inch diameter spherical steel electrodes with a gap of 0.20 inch are tabulated in Table II.

During irradiation there is no evidence that the d-c electric strength is less than the strength when not exposed to radiation. The above data indicate the electric strengths of fluids previously exposed to radiation are greater during irradiation. The individul data also show that irradiation improves the consistency of the breakdown voltages of these previously irradiated fluids.

Radiation Effects on Compounds

Silicone compounds, manufactured by introducing substantial amounts of inorganic fillers into silicone fluids, are used as sealing compounds in electrical and electronic apparatus and components and as a water repellent surface coating for ceramic insulators.[12] The effects of gamma radiation on silicone compounds are demonstrated by data on two such compounds. Both compounds use silica fillers and differ primarily in the silicone fluids used.

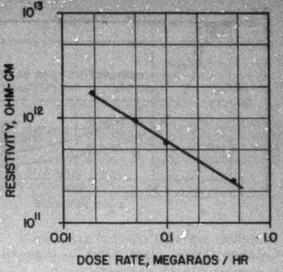

Fig. 7. Resistivity of 100-cs dimethyl silicone fluid during irradiation

Compound A—Dimethyl silicone fluid base, silica filler (Dow Corning 4 Compound)

Compound B—Phenylmethyl silicone fluid base, silica filler (Dow Corning 5 Compound)

Since inorganic fillers are relatively unaffected by radiation doses of 1,000 megarads or less, effects of radiation on these silicone compounds are due to radiation effects on the fluid base and possible radiation induced reactions between the fluid and filler. Many of the effects observed would be predictable knowing the basic characteristics of these silicone compounds and the previously discussed effects of radiation on silicone fluids.

PHYSICAL PROPERTIES

The consistency of these compounds is affected by relatively small radiation exposures, as is shown in Fig. 8. The dimethyl fluid-based compound hardens rapidly and then gels after a dose of approximately 25 megarads. The phenylmethyl fluid-based compound behaves in a similar manner except a larger dose is required to achieve the same effects.

Table II. Breakdown Voltage

		Average Breakdown Voltage, Kv	
Silicone Fluid, Cs	Previous Dose, Megarads	0.00 Megarads/ Hour	0.17 Megarad/ Hour
100, dimethyl	0	11.0	12.0
	50	8.3	11.8
40, phenylmethyl	2	12.0	11.8
	100	7.7	12.0

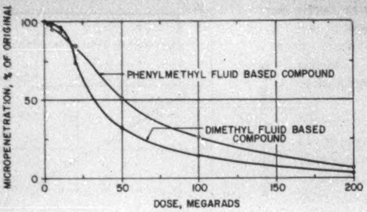

Fig. 8 (left). Consistency of two silicone compounds after irradiation

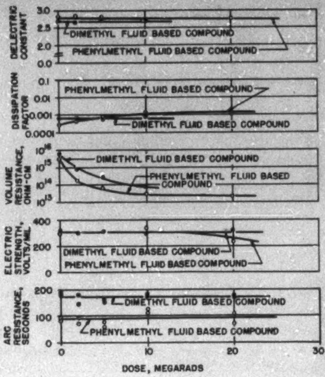

Fig. 9 (right). Dielectric properties of silicone compounds after irradiation

Gelation takes place after a dose of approximately 40 megarads.

After a dose of 200 megarads, both compounds become brittle gels. However, there is no visible evidence of shrinking or cracking even after 1,000 megarads of irradiation.

Similar to the phenylmethyl silicone fluids, the phenylmethyl fluid-based compound becomes amber colored upon radiation exposure. This is more apparent at the surface of the compound which is in contact with air. Apparently the discoloring reaction is between the phenyl groups in the compound and air. No change in color takes place in the dimethyl fluid-based compound even after 1,000 megarads of irradiation.

Dielectric Properties

The permanent effects of gamma radiation on the dielectric properties of silicone compounds are similar to those of silicone fluids. These effects are shown in Fig. 9.

Radiation doses less than the gelation dose have no appreciable effect upon the dielectric constant of either of these two silicone compounds. This radiation also has no effect no the dissipation factor of the dimethyl fluid-based compound; however, it causes a slight increase in the dissipation factor at 100 cps for the phenylmethyl fluid-based compound.

Radiation decreases the resistivity of both types of compounds. The resistivity of the phenylmethyl fluid-based compound was decreased a hundred fold by a dose of 10 megarads.

Fig. 9 shows that radiation has little effect on the electric strength. However, data in Table III for doses greater than the gelation dose show that the electric strength is sharply reduced by greater irradiation doses. The phenylmethyl fluid-based compound is more resistant in this regard; a dose greater than 200 megarads is required to achieve this decrease in electric strength.

The drop in electric strength by irradiation beyond gelation indicates that the physical integrity of the compound may be affected. This is not evident from visual observation since the defects are apparently microscopic in size.

Both Fig. 9 and Table III show that irradiation has little effect on the arc resistance of either silicone compound.

No measurement of the dielectric properties of silicone compounds has been made during radiation exposure. However, in view of the similarity in permanent effects of radiation on silicone compounds and fluids, it is expected that the transitory dielectric properties, which occur during irradiation, may also be similar.

Radiation Effects on Elastomers

Silicone elastomers are produced by introducing substantial amounts of inorganic fillers into high molecular weight silicone fluids and then vulcanizing, or cross-linking the polymer.[13] These elastomers are noted for retention of physical and dielectric properties during and after high- and low-temperature exposures. The primary effects of gamma radiation on silicone elastomers are demonstrated by data on five stocks in Table IV.

Physical Properties

Gamma radiation at 25 C hardens silicone elastomers and reduces the flexibility and tensile strength; Fig. 10 shows these effects for one silicone elastomer. These data are representative of a majority of the silicone elastomers. Elongation is the property most affected. It is reduced by 80% after 100 megarads of irradiation. After 500 megarads, the physical properties are essentially de-

Table IV. Data on Silicone Elastomers

Elastomer (Silastic)	Polymer, Silicone	Typical Dielectric Application
80	Dimethyl	Molded parts, wire insulation
S-2048	Phenylmethyl	Molded parts
132	Dimethyl	Cloth coating
S-2007	Dimethyl	Heat vulcanized encapsulant
RTV S-5313, S-5314	Dimethyl	Room temperature vulcanized encapsulant

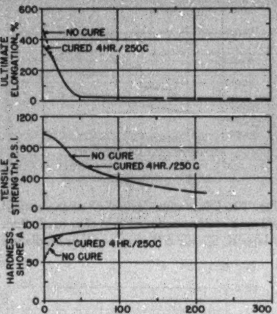

Fig. 10. Some physical properties of a typical silicone elastomer after irradiation. Material, Silastic 80

stroyed for most dielectric applications. Phenylmethyl-type silicone elastomers, such as Silastic* *S-2048*, have no marked improvement in resistance to these radiation effects.

Although the physical properties of silicone elastomers are severely damaged by doses as low as 50 megarads, many applications for these materials as dielectrics do not require extreme elongation and tensile strength. In such applications as coil insulation and encapsulants for electronic assemblies, silicone elastomers may be usable after doses as great as 200 to 500 megarads at 25 C.

Radiation has a permanent effect on the density of Silastic *RTV, S-5313, S-5314*. The density is increased by approximately 6% as the material shrinks after 100 megarads exposure. This may be a severe effect since the tensile strength is also damaged by irradiation. This large effect of radiation on density has not been observed for any other silicone elastomer.

DIELECTRIC PROPERTIES

Gamma irradiation produces both permanent and transient effects on the dielectric properties of silicone elastomers.

Permanent Effects. Gamma irradiation increases the dielectric constant of silicone elastomers. Fig. 11(A) shows this increase is largely a linear function of the irradiation dose and thus the dielectric constant of irradiated silicone elastomers can be expressed mathematically by equation 4:

$$K = K_0 + \beta_k D \qquad (5)$$

Values of β_k, the coefficient of increase in dielectric constant, have been calculated for frequencies of 100 cps and 10 mc/sec and temperature of 23 C.

Elastomer (Silastic)	β_k, Megarad^{-1}	
	100 Cps	10 Mc/Sec
Silastic *80*	0.00075	0.00057
Silastic *S-2048*	0.0000	0.0000
Silastic *S-2008*	0.0025	0.00093

Table V. Values of β_δ

Stock (Silastic)	β_δ, Megarad^{-1}	
	100 Cps	10 Mc
80	0.0015±0.0004	0.0015±0.0004
S-2048	0.0003±0.0002	0.0007±0.0002
S-2007	0.0025±0.0004	0.0011±0.0004
RTV S-5313, *S-5314* (after 40 megarads)	0.0000±0.0003	0.0000±0.0003

These data indicate that the radiation effects are more pronounced at 100 cps. However, regardless of the type of silicone elastomer, a dose of at least 200 megarads is required to increase the dielectric constant by 0.5; hence, for most insulating applications, radiation exposure has little effect on the dielectric constant of silicone elastomers.

Radiation exposure also increases the dissipation factor. Fig. 11(B) shows that the increase in dissipation factor can be expressed mathematically

$$\log\left(\frac{\tan\delta}{\tan\delta_0}\right) = \beta_\delta D \qquad (6)$$

when $\tan\delta$ is the dissipation factor, $\tan\delta_0$ is the dissipation factor prior to irradiation, β_δ is the coefficient of increase in dissipation factor, and D is the irradiation dose.

Values of β_δ at 100 cps and 10 mc/sec at 23 C temperature are shown in Table V.

These data indicate that considerable

A—During and after irradiation
B—During irradiation

variation in radiation resistance exists among different silicone elastomers. However, for the silicone elastomers investigated, the dose required to double the 100-cps dissipation factor is 120 megarads or greater; at 10 mc/sec, at least 200 megarads is required. Thus, radiation exposure has no great permanent effect on the dissipation factor of silicone elastomers for most applications.

Radiation also has little effect on the resistivity of silicone elastomers as is shown by Fig. 11(C).

A similar lack of significant effect is shown in Fig. 11(D) which indicates radiation exposure does not decrease the 60-cps electric strength of silicone elastomers. Data on several other irradiated silicone elastomers also indicate the electric strength is not damaged unless the physical integrity is first destroyed.

Transient Effects. The dielectric properties of several different stocks of silicone elastomers were measured during irradiation.

No transitory effect of irradiation on the dielectric constants of Silastic *80*, a dimethyl elastomer, and Silastic *675*, a phenylmethyl silicone elastomer, were observed.

A transitory effect on the dissipation factor was measured; this effect was opposite in direction to that observed with silicone fluids. Fig. 12(A) shows that the dissipation factor of a dimethyl silicone elastomer decreases with increasing radiation intensity. This effect is pronounced at 100 cps but decreases with increasing frequencies and is not easily observed at 10,000 cps at dose rates of 0.1 megarad/hour or less.

No explanation for this effect is offered except that by some mechanism the absorbed radiation energy apparently reduces either the charge or mobility of large charged regions of the material.

Fig. 12(B) shows that the dissipation factor of this silicone elastomer during irradiation does not follow a simple relationship as was found for silicone fluids.

Similar measurements were also made on Silastic *675*, a phenylmethyl silicone elastomer. Data obtained show that in addition to the general effects on a dimethyl elastomer, there is a time-dependent effect both during and immediately after irradiation. As indicated in Fig. 13, the magnitude of this time-dependent effect during irradiation is essentially the same as that immediately after irradiation. The time constant of this effect is approximately 6.5 minutes for irradiation exposures of 10 to 20 minutes at dose rates from 0.02 to 0.2 megarad/hour.

It is suggested that this effect is due to products of radiation-induced reactions involving the phenyl groups of the silicone elastomer. Since products of the phenyl groups may be expected to be larger than those of methyl groups, less mobility may result. This would then require a longer time before these activated products achieve their annihilating reaction.

Fig. 14 shows that for this phenylmethyl elastomer, the dissipation factor is relatively unaffected during irradiation after this time effect takes place. It can be readily seen in both Figs. 12(B) and 14 that the dissipation factor of these silicone elastomers is essentially not damaged in a transient manner during irradiation.

Volume resistivity measurements conducted on both of these elastomers during irradiation showed that this property remained greater than 0.5×10^{14} ohm-cm, the limit of the measuring apparatus.

The electric strength during irradiation is also an important engineering property. In order to measure the electric strength of a silicone elastomer during irradiation with portable measuring equipment, thin samples which would break down at less than 14 kv were required. Glass cloth 0.004 inch thick, coated to a total thickness of 0.010 inch with Silastic *132*, a cloth-coating silicone elastomer, was used for this study.

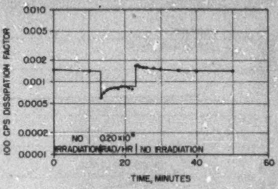

Fig. 13. Dissipation factors of phenylmethyl silicone elastomer during and after irradiation. Material, Silastic 675; no previous irradiation

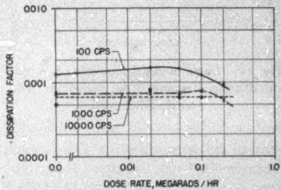

Fig. 14. Dissipation factor of phenylmethyl silicone elastomer during irradiation. Material, Silastic 675; 5 minutes previous irradiation

Electric strength data often follow an extreme value statistical distribution.[14,15] Data from these measurements were therefore plotted on extreme value probability paper. Fig. 15 shows that at a dose rate of 0.06 megarad/hour, the 60-cps electric strength is not significantly different from that prior to the radiation exposure. Not only is there a lack of effect on the modal value of electric strength, but there is little effect on the statistical consistency of the individual breakdown voltages.

Radiation Effects on Resins

Silicone resins, which are highly cross-linked silicone polymers, are widely used dielectrics as laminating resins, cloth-coating resins, impregnating and bonding varnishes, and in the manufacture of magnet wire.[16]

In most of these applications the silicone resin is used in combination with an inorganic material, often glass fiber or cloth. Since it is difficult to prepare samples of pure silicone resin, studies of the effects of radiation on silicone resins are made using simple insulation systems of resins and appropriate inorganic materials.

The behavior of silicone resins during and after exposure to radiation is demon-

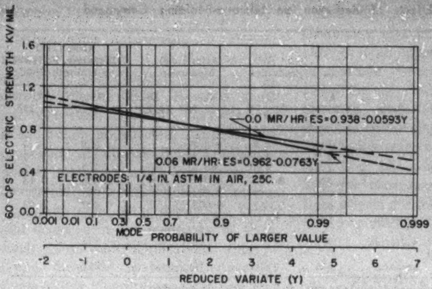

Fig. 15. Electric strength of silicone elastomer coated glass cloth before and during irradiation. 0.004-inch cloth coated with Silastic 132 to 0.010 inch thickness

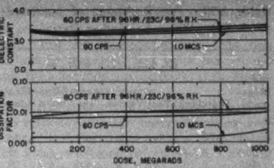

Fig. 16. Dielectric constant and dissipation factor of silica-filled silicone resin after irradiation

strated by data on four simple resinous insulating systems:

Resin	Dow Corning	Inorganic Material
Solventless resin	*R-7521*	Silica flour
Cloth-coating resin	*994* (varnish)	Glass cloth
Molding compound	*301*	Chopped glass fiber
Laminating resin	*2105 A*	Glass cloth

PHYSICAL PROPERTIES

Measurements on irradiated samples of silica-filled solventless silicone resin provide no evidence that irradiation doses up to 1,000 megarads affect the flexural strength. These data are listed in Table VI.

The only salient effect of radiation exposure on the physical properties of these resins is a decrease in flexibility of the glass cloth-resin systems after 500 and 1,000 megarads of irradiation. This is evidence of extensive radiation-induced cross-linking of the resin. However, the irradiated glass cloth insulating systems were easily flexed over a small mandrel which shows the ultimate elongation of the irradiated resins is greater than 2%.

One other effect, but of little engineering importance, is a noticeable darkening of the color of the solventless resin by doses of 500 megarads and greater.

Table VI. Flexural Strength of Irradiated Silica-Filled Solventless Resin

Dose, Megarads	Flexural Strength, Psi				Average Flexural Strength, Psi
0	8,940	8,100	8,400		8,480
200	8,580	7,650	7,970		8,067
500	8,700	7,780	8,720		8,400
1,000	8,100	8,220	8,200	7,940	8,115
				Average:	8,254±260

Test: ASTM *D790-49T*.
Subject: Approximately 4×1×1/8 inch slabs.

DIELECTRIC PROPERTIES

Similar to the effects on silicone elastomers, radiation has some, but few permanent, effects on the dielectric properties of silicone resin systems. The transient effects, however, are similar to those present with silicone elastomers.

Permanent Effects. Irradiation causes a slight increase in the dielectric constant of silicone resins as demonstrated by Fig. 16 for the solventless resin. Even after a dose of 1,000 megarads the increase in dielectric constant of silica-filled solventless resin at frequencies from 60 cps to 100 mc is so small as to be of little engineering significance. This figure also shows that the dielectric constant of irradiated solventless silicone resin is little affected by additional moisture exposure. This indicates irradiation does not greatly affect the water adsorption characteristics of the volume of the silicone resin.

An irradiation dose of 500 megarads has no appreciable effect on the dissipation factor of the solventless silicone resin at frequencies from 100 cps to 10 mc. However, as is also shown in Fig. 16, irradiation from 500 to 1,000 megarads increases the dissipation factor; after 1,000 megarads the 60-cps dissipation factor is approximately 0.01.

Fig. 17 shows that irradiation has no appreciable effect on the electric strength of the solventless silicone resin unless the dose exceeds 500 megarads. An additional 500 megarads, however, increases the rapid-rise electric strength by more than 60%; the 1-kv-per-minute step-by-step electric strength is also increased about 25%. The rate of voltage rise has no appreciable effect on the electric strength for irradiation doses of 500 megarads and less. Thus, irradiation beyond 500 megarads affects the voltage endurance relationship.

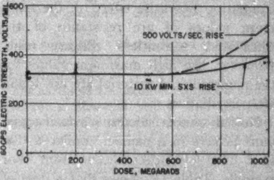

Fig. 17. Electric strength of silica-filled silicone resin after irradiation

Data given in Table VII, for this resin system after 1,000 megarads of irradiation, indicate that the electric strength with a slower rate of voltage rise would be less than with a 1-kv-per-minute rise. Subsequent data for 1-kv-per-10-minute rate of voltage rise show that this is true; however, electric strength under these conditions is still greater than the strength of the samples irradiated 500 megarads. Thus, although irradiation affects the electric strength of a silicone resin system, the effects are not damaging.

Table VII. Breakdown Voltage of Irradiated Silica-Filled Solventless Resin

		Breakdown Voltage, Kv								
Dose, Megarads	Thickness, Inches	500 Volts per Second	1 Kv per Minute, Step by Step			1 Kv per 10 Minutes, Step by Step				Electric Strength, Volts per Mil for 1 Kv per Minute Rise
0	130	40	43	40	43	41				322
200	122	42	41	43	40	40				336

† Beyond range of measuring techniques used.

The data in Table VIII show that irradiation has little effect on the minimum values of arc resistance of the silica-filled solventless silicone resin. However, the high maximum values for the nonirradiated material are not found after irradiation.

Not all simple silicone insulating systems behave in a manner similar to the silica-filled solventless silicone resin. For example, Table IX shows that a dose of 1,000 megarads has a sizeable effect on the dielectric constant, dissipation factor volume resistivity, and electric strength of a silicone molding compound. Irradiation reduces the water resistance of this material. Much of this irradiation damage is removed, however, by subsequent high-temperature exposure. Table IX shows that a 1-month exposure at 300 C restores most of these properties.

Transient Effects. Dielectric constant dissipation factor, and volume resistivity measurements made on a silicone-glass laminate during and immediately after irradiation were similar to those made on silicone elastomers.

No transient effect on the dielectric constant was observed.

As shown in Fig. 18, the effect on dissipation factor is similar to that on a dimethyl silicone elastomer. Although the laminating resin contains phenyl groups, no time-dependent effect was observed. Similar to the elastomers, the decrease in dissipation factor during irradiation is more pronounced at the lower frequencies:

Frequency, Cps	Dissipation Factor: 0.0 Megarads/Hour	Dissipation Factor: 0.2 Megarads/Hour
100	0.0024	0.0004
1,000	0.0030	0.0012
10,000	0.0013	0.0014

During irradiation at dose rates up to 0.2 megarad/hour, the volume resistivity remained greater than 0.3×10^{14} ohm-cm, the limit of the measuring system and slightly less than the resistivity prior to the radiation exposure.

The electric strength of silicone resins during irradiation is also an important property. To measure this characteristic, 0.004-inch-thick glass cloth coated with a silicone cloth coating resin was used. Data from these measurements were plotted in Fig. 19 on extreme value probability paper. These data show that dose rates up to 0.15 megarad/hour have no appreciable effect on the modal value of the electric strength. Furthermore these data show a possible increase in the consistency of the breakdown voltages with increase in radiation intensity.

Conclusions

Irradiation ionizes silicone dielectrics causing rearrangement of the chemical structure and the production of impurities. This rearrangement of the chemical structure causes major effects on the physical properties.

The rearrangement and the impurities produced have significant effects on some of the dielectric properties. Since some of the impurities are transitory, some of the effects are also transitory, while others are permanent. These transitory effects in silicone dielectrics are often larger than the permanent effects and occur during and for some silicones immediately after irradiation. The transitory effects may limit the performance of silicone fluids as dielectrics during radiation exposure.

In general, the physical properties of silicone fluids, compounds, elastomers, and resins are damaged by irradiation before the essential dielectric properties are significantly and permanently affected. Therefore, the effects of irradiation upon the physical properties are the primary factors in limiting the performance of silicone dielectrics after radiation exposures.

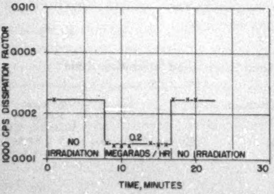

Fig. 18. Dissipation factor of silicone-glass laminate during and after irradiation. Sample received no previous irradiation

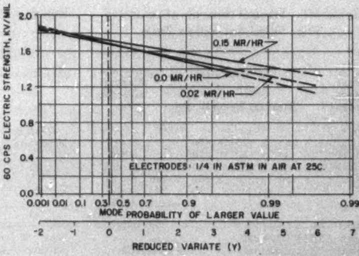
Fig. 19. Electric strength of silicone resin coated glass cloth before and during irradiation. Dow Corning 936 Resin coated on 0.004-inch glass cloth to 0.008-inch thickness



Silicone Fluids

Other than a decrease in electric strength, radiation at 25 C causes few effects on the dielectric properties of dimethyl silicone fluids. However, physical properties, primarily viscosity and gas evolution, are affected. The physical properties of silicone fluids containing phenyl groups are much less affected by irradiation; however, irradiation causes a drastic increase in the dissipation factor and decrease in the resistivity of these fluids. For those applications where a liquid dielectric is required dimethyl fluids of low viscosity are most practical and may be usable for doses up to 100 megarads.

Silicone Elastomers

Irradiation doses less than 200 megarads have little significant effect on the dielectric properties of silicone elastomers. The physical properties of silicone elastomers, however, are affected by relatively low doses. After a dose of 100 megarads, a majority of the flexibility of the elastomer is destroyed. For those numerous applications in electrical and electronic apparatus where extreme flexibility is not required once the elastomer is in place, silicones may be suitable for doses of 200 to 500 megarads.

Silicone Resins

Silicone resins, in general, are much more resistant to radiation than silicone fluids and elastomers. The major dielectric properties of a solventless silicone resin are not damaged by gamma irradiation doses as high as 1,000 megarads. These doses also have no significant effect on the physical integrity or strength of this material. Although the radiation resistance of this material is believed to be typical of those on most silicone resins, radiation has been found to destroy important dielectric properties of one silicone molding compound. These dielectric properties, however, are restored to a considerable degree by subsequent high-temperature exposure.

Dielectric Properties During Irradiation

The dielectric constant of all silicone dielectrics tested remains essentially the same during irradiation as before. Electric strength is likewise unaffected.

The electrical losses are affected, however. The dissipation factor of silicone fluids at 100 cps and 1,000 cps may be 10 to 100 times normal when irradiated at a dose rate of 0.1 megarad/hour. The resistivity is likewise affected.

The dissipation factor of silicone elastomers and at least one resin are affected in an opposite manner, however. With these dielectrics, the dissipation factor during irradiation decreases with increasing radiation intensity at frequencies below 10,000 cps.

Although some time-dependent effects have been observed with silicone fluids and one elastomer, the magnitudes of these effects are relatively small and the time constant less than 10 minutes.

Appendix. Samples and Test Methods

Unless otherwise noted, all radiation exposures are made at 25±3 C and at a dose rate of 0.5 to 0.7 megarad/hour. Measurements are in general made at 23±1 C in accordance with applicable ASTM (American Society for Testing Materials) standards:

Property	ASTM Standard Test Method
Dielectric constant	D150-54T
Dissipation factor	D150-54T
Volume resistivity	D257-57T
Electric strength	D149-55T
Arc resistance	D495-56T
Flexural strength	D790-49T

Fluid samples consist of 3 ounces of fluid in 4-ounce bottles vented through small holes in the caps. These samples are irradiated at a dose rate of 0.3 megarad/hour. Compounds are placed in 2-ounce tin ointment cans, $2^3/_8$ inches diameter by 3/4 inch deep, and cover applied.

Elastomers are press molded into sheets approximately 0.10 inch thick and cut into slabs $3^1/_2 \times 8$ inches. Resin systems are cast or molded into samples approximately 0.125 inch thick and 3 to 10 square inches in area. The resin samples are wrapped in 0.006-inch-thick aluminum foil prior to radiation exposure.

Measurements After Irradiation

Dielectric constant, dissipation factor, and volume resistivity measurements are made using the same cell: fluids, J. C. Balsbaugh type *2TN25* cell (2-element); compounds, 2-element cell with vacuum capacitance of 35 micromicrofarads; elastomers and resins, the General Radio Company type *1690-A* Sample Holder (2-element). Measurements are made at 50, 10^2, 10^3, 10^4, 10^5 cps using General Radio type *716-C* Schering Bridge and appropriate auxiliary apparatus. These measurements are also made at 150 C on the fluid samples. Measurements are made at 1 and 10 megacycles/second using a susceptance variation circuit, and in the case of fluids and compounds, a special 2-element cell. Resistivity measurements are made using a Federal Telephone and Radio type *H* Terraohmmeter. An electrification period of 1 minute is used and the test potential is 500 volts.

Electric strength of irradiated fluids and compounds are made using 0.500-inch-diameter spherical steel electrodes. For fluids, the d-c test voltage is applied step-wise 1.0 kv per minute and the electrode gap is 0.020 inch. For the compounds, the cps test voltage is increased 500 volts per second and the electrode gap is 0.050 inch except for the gelled specimens.

Electric strength of irradiated elastomer and resin samples are measured using 1/4-inch ASTM electrodes on oil. The 60-cps test voltage is increased step-wise 1 kv per minute except where otherwise noted with these data.

Arc resistance is measured using pointed electrodes for the compounds and elliptical electrodes for the resin samples. The electrode gap is 0.50 inch.

The viscosity of irradiated fluids is measured using a capillary viscosity pipette or a Brookfield model *LVF* viscometer. The density is measured using Fisher hydrometers.

The consistency of irradiated compounds is measured using a precision scientific micropenetrometer.

The hardness of elastomer samples is measured on a Shore *A* scale. The ultimate elongation and tensile strength are measured using an Instron model *TM* tensile tester.

The flexural strength of irradiated solventless resin samples are measured using a Baldwin Universal Tester.

Measurements During Irradiation

Dielectric constant, dissipation factor, resistivity, and electric strength of fluid, elastomer, and resin samples are also measured during irradiation.

A J. C. Balsbaugh *3TN25* 3-terminal cell is used for complex permittivity and resistivity measurements of silicone fluids. Elastomer and resin samples, 2 inches in diameter, are placed in a guarded 3-terminal cell with thin aluminum electrodes having an active surface of 1.500 inches in diameter. These cells and the lead connections are completely submerged in Dow Corning 200 fluid, 250 cs during the measurements. The elastomer and resin samples are wetted with this silicone fluid to insure an absence of air pockets next to the electrodes. Guarded leads are used between the measuring instruments outside of the "cave" and the electrodes. Dielectric constant and dissipation factor are measured using an Electro-Measurements model *270* capacitance bridge at 100, 1,000, and 10,000 cps; resistivity is measured using a General Radio model *544-B* megohm bridge.

The electric strength of fluids during irradiation is measured by the same procedure as detailed for irradiated fluids after irradiation. The electric strength of elastomer and resin coated glass cloth is measured using 1/4-inch ASTM electrodes in air. The 60-cps test voltage is increased at a rate of 200 to 500 volts per second.

The shielding effect of the sample holders is considered in the orientation of the sample and in the calculation of the dose rate.

Mathematics of Insulation-Aging Calculations

L. C. WHITMAN
FELLOW AIEE

W. W. WHITMAN
NONMEMBER AIEE

Synopsis: Equations are developed for the calculation of insulation aging in apparatus, in which it is recognized that the temperature of the apparatus usually changes in accordance with an exponential relation. The results from this method are compared with the simplification usually made of assuming rectangular temperature cycles and also with the assumption of a triangular temperature cycle. Insulation aging rate is based on the use of the Arrhenius chemical reaction rate theory, which relates insulation deterioration to the reciprocal of the absolute temperature. All aging values are in terms of relative aging, which assigns a value of unit aging to a specified temperature. To establish the errors involved in the simplifying assumptions conventionally used in aging computations, the calculations in this paper are carried out to more significant figures than basic aging data and time constants would justify.

THE TRANSIENT temperature of most electric apparatus, for the condition of increasing temperature, can usually be quite accurately expressed as an exponential function of time[1,2] as follows (Appendix I gives the nomenclature):

$$T=T_0'+A\,(1+\epsilon^{-\alpha t}) \qquad (1)$$

Also in the cooling of electrical apparatus the transient temperature can be similarly expressed as

$$\begin{aligned} T&=T_1-D\,(1-\epsilon^{-\alpha t})\\ &=T_0'+D\epsilon^{-\alpha t} \qquad (2)\end{aligned}$$

A typical example of the transient temperature of electric apparatus through one load cycle is shown in Fig. 1, assuming a load $=L_1$ from t_0 to t_1 and a load L_0 from t_1 to t_n. L_0 is here the steady-state load existing for a length of time previous to t_0 to establish an equilibrium temperature condition at t_0.

The examples given in this paper assume that the time constant is the same in equations 1 and 2. This is approximately true for air-cooled apparatus where there is a single thermal gradient from the apparatus to the cooling medium (air). In liquid-cooled apparatus this is not so since there are essentially two thermal gradients in series (apparatus to liquid and liquid to air) with quite different time constants.

Under transient temperature conditions insulation-aging rates are continuously changing throughout the load cycle. Simplifying assumptions concerning temperature are usually made to simplify these aging calculations. The simplest assumption (illustrated in Fig. 2) is that the shaded portions of Fig. 1 (or at least their effects) are equal. For the case shown the shaded areas differ by some 67%, and still differ by about 8% for the case of $t_1=10$ hours, becoming equal only when both t_1-t_0 and $t_{24}-t_1$ are infinite.

The insulation aging from time t_0 to t_{24} under the conditions of Fig. 1 is also quite different from that shown for the same time interval in Fig. 2. It will later be shown that this assumption leads to answers too large for large time intervals t_0 to t_1 and to answers too small for shorter time intervals.

An alternate assumption is shown in Fig. 3. In this case the answers for insulation aging will invariably be too low, irrespective of the length of time that L_1 exists, or of apparatus time constant. The magnitude of this error will be later shown for some illustrative cases.

Relative Insulation Aging

It is generally recognized that most insulations deteriorate in accordance with the chemical reaction rate theory.[3] From this it follows that deterioration rates of insulation are generally straight lines when the reciprocal of the absolute temperature of the insulation are plotted as abscissas and logarithms of life in time unit (hours or years) are plotted as ordinates. It is difficult to obtain data or to obtain agreement regarding the end of life of insulation. To make this study perfectly general it is thus convenient to use a relative insulation-aging curve instead of an absolute one. Such an approach requires only knowledge of the aging rate for a particular insulation and the assignment of unit aging to a definite reference temperature. Representative relative aging rate curves are given for two different types of insulation for two different reference temperatures together with data for the rates used in determining the slopes of these curves (given in references 4 and 5). The reference temperatures are 10 degrees lower than the maximum hottest spot temperatures allowed for these classes of insulations, corresponding to an average ambient of 30 C (degrees centigrade) over 24 hours, rather than a maximum

Vol.
Pt. 1
1959

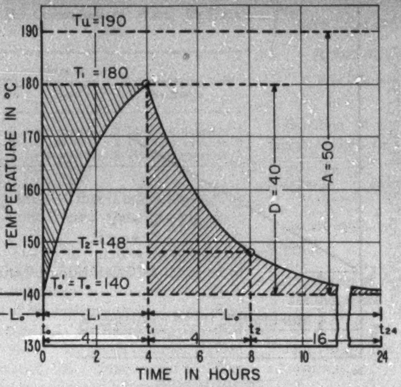

Fig. 1. Typical example of transient temperature of electric apparatus: case 3 in calculations

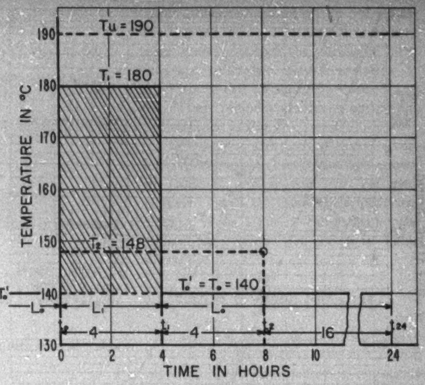

Fig. 2. A simplifying assumption of the transient temperature cycle of Fig. 1 often used in aging calculations. Case 1 in calculations

ambient of 40 C over 24 hours. These relative aging curves from reference 4 are shown in Fig. 4.

The equation for these curves is

$$\ln R = b\left[\frac{1}{T_0} - \frac{1}{T}\right] \qquad (3)$$

Equations will now be developed covering insulation aging for the cases of rectangular, triangular, and exponential temperature cycles and computations made illustrating the variation in results.

Rectangular Time-Temperature Cycle: Case 1, Fig. 2

Case 1 is quite simply calculated. As an illustrative example, assume

$T_0 = 140 + 273 = 413$ K (degrees Kelvin)
$T_1 = 180 + 273 = 453$ K
$t_1 - t_0 = 4$ hours
$t_{24} - t_1 = 20$ hours

Also assume relative aging curve *B* in Fig. 4, where $b = 11{,}500$; relative aging at 180 C from Fig. 4 = 12.

This may be more accurately determined by the use of equation 3, which gives the value 11.69 (with assumed values just given of temperature and $b = 11{,}500$). To compute cumulative relative aging over the 24-hour cycle assumed in Fig. 2 the relative aging at each temperature must be multiplied by the elapsed hours at the given temperature. Note that relative aging at the assumed reference temperature of 140 C equals 1 (from the definition of relative aging). The cumulative aging from t_1 to t_{24} then equals $(1)(20) = 20$.

Hence, hours' cumulative relative aging over the 24-hour temperature cycle in Fig. $2 = (4)(11.69) + 20(1) = 66.8$. The reference aging for 24 hours is obviously $(24)(1) = 24$.

$$\text{Relative aging over 24-hour temperature cycle} = 66.8/24 = 2.78 \qquad (4)$$

This means that if such a temperature cycle is repeated daily the insulation system will have 1/2.78 of the hours of life it would have with a continuous temperature of 140 C.

Triangular Time-Temperature Cycle: Case 2, Fig. 3

Case 2 would appear to be a simple calculation but it is actually quite involved since it requires integration under a relative aging curve. A general solution for this case is given in Appendix II, as shown in equation 40.

This general solution involves exponential integrals for which tables are available[6] for values of *x* between between zero and 15, and[7] between 20 and 50, with a region for *x* between 15 and 20 with no available tables. A simplified expression may be used which has an error of less than 1.0% for $x > 10$ (*x* is expressed in equation 40 by *u*) with the error decreasing to less than 0.05% for $x > 20$. In the particular example (and in most cases encountered) the limits *u* and u_0 on the integral are greater than 20, so the simplified equation 43 in Appendix II is applicable. Also, in Fig. 3, $T_0' = T_0$, so that the more general case given by equation 43 (as

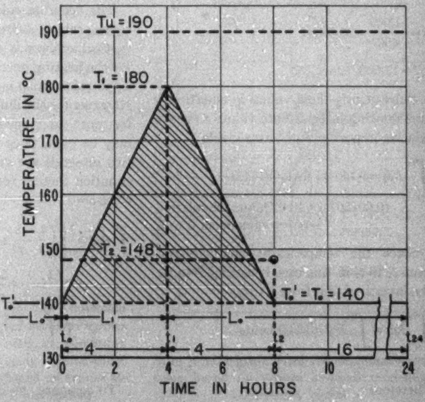

Fig. 3 Alternate simplifying assumption of the transient temperature cycle of Fig. 1 which might be used in aging calculation. Case 2 in calculations

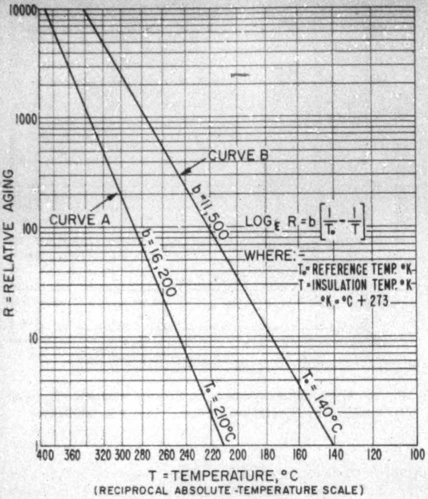

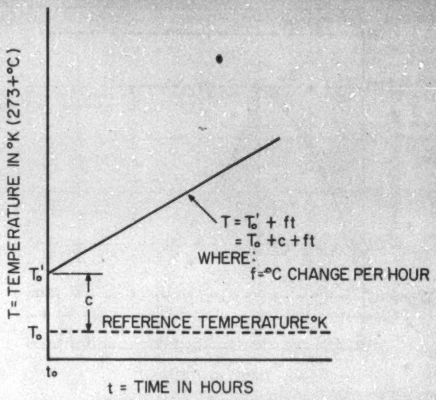

Fig. 4 (left). Representative relative aging curves for two different types of insulation for two different reference temperatures

Fig. 5 (above). Time-temperature relations for a constant rate of temperature change; see Appendix II for insulation aging equations

derived from Fig. 5) reduces to equation 44 (Appendix II) which is

$$\int_0^t R\,dt = \frac{b}{f}\left[\epsilon^{u_0-u}\left(\frac{1}{u^2}-\frac{2}{u^3}+\frac{6}{u^4}\right)-\left(\frac{1}{u_0^2}-\frac{2}{u_0^3}+\frac{6}{u_0^4}\right)\right] \quad (5)$$

To make a comparison of cases 1 and 2 assume the same values of these quantities as in Case 1; then

$$f = \frac{T_1 - T_0}{t} = \frac{453-413}{4}$$

$= 10$ C per hour temperature change

$$u_0 = \frac{11{,}500}{413} = 27.84504$$

$$u = \frac{11{,}500}{453} = 25.38631$$

$b/f = 11{,}500/10 = 1{,}150$

Substituting these values in equation 5 and showing intermediate values to show relative importance of terms yields

$$\int_0^{t_1} R\,dt = 1{,}150[11.69(0.001445) - (0.001207)] = 18.02$$ hours cumulative relative aging from t_0 to t_1

Since the temperature characteristic from t_1 to t_2 in this case is assumed to be the inverse of that from t_0 to t_1,

$$\int_{t_1}^{t_2} R\,dt = \int_0^{t_1} R\,dt = 18.02 \text{ hours}$$

cumulative relative aging from t_1 to t_2

Therefore

$$\int_0^{t_2} R\,dt = 18.02 + 18.02 = 36.04 \text{ hours}$$

cumulative relative aging from t_0 to t_2

The cumulative relative aging from t_2 to $t_3 = (1)(16) = 16$ hours. Hence the cumulative relative aging over the 24-hour temperature cycle in Fig. 3 $= 36.04 + 16 = 52.04$ hours. Therefore

Relative aging over the 24-hour temperature cycle of Fig. 3 $= \frac{52.04}{24} = 2.17$ (6)

Exponential Time-Temperature Heating Cycle: Case 3a, Fig. 1

The accurate calculation of case 3a is considerably more involved. Mathematical analysis is given in Appendix III for the heating portion of the cycle where a general solution is shown in equation 78. However for the illustrative example (and for most cases encountered) equation 79 may be used, since the limits on the first two integrals are greater than 10. This equation further reduces to equation 80, since $c=0$.

$$\int_0^t R\,dt = \frac{1}{\alpha}\left[\left(\frac{1}{p}-\frac{1}{p^2}+\frac{2}{p^3}-\frac{6}{p^4}\right) - \epsilon^{p-s}\left(\frac{1}{s}-\frac{1}{s^2}+\frac{2}{s^3}-\frac{6}{s^4}\right) - \epsilon^{p-r}\left(\int_{p-r}^{\infty}\frac{\epsilon^{-y}}{y}\,dy - \int_{s-r}^{\infty}\frac{\epsilon^{-y}}{y}\,dy\right)\right] \quad (7)$$

To compare the insulation aging based on exponential temperature change with the examples given in cases 1 and 2, values of $\alpha = 0.4$ and $A = 50$ were selected so that for case 3 the value of T_1 at the end of $t_1 = 4$ hours agreed closely with the value of T_1 assumed in cases 1 and 2. These values with the previously assumed value of b and T_0 in cases 1 and 2 give

$$\frac{1}{\alpha} = 2.5$$

$$A = 50$$

$$T_1 = 452.905$$

$$p = \frac{11{,}500}{413} = 27.84504$$

$$r = \frac{11{,}500}{50+413} = 24.83801$$

$$s = \frac{11{,}500}{413+50(1-\epsilon^{-(0.4)(4)})} = 25.39164$$

Substituting these values in equation 7 and showing intermediate values to show the relative importance of terms yields

$$\int_0^{t_1} R\,dt = 2.5[(0.034726) - 11.6278(0.037940) - 20.230(0.012932 - 0.49957)]$$

$= 23.688$ hours cumulative relative aging from t_0 to t_1 (8)

Equation 7 contains exponential integrals of the form

$$-Ei(-x) = \int_x^{\infty}\frac{\epsilon^{-y}}{y}\,dy \quad (9)$$

These are evaluated by tables in references 6 and 7.

Table I. Comparison of Aging for Three Cases

Case No.	Fig. No.	Type of Temperature Cycle	Relative Aging Over 24 Hours
1	2	rectangular	2.78, from equation 4
2	3	triangular	2.17, from equation 6
3	1	exponential	2.412, from equation 13

Exponential Time-Temperature Cooling Cycle: Case 3b, Fig. 1

For case 3b, to complete the calculation of the aging of the insulation subjected to the temperature cycle in Fig. 1, use is made of the mathematical analysis given in Appendix IV for the cooling portion of the cycle, where a general solution is given in equation 110. However, for the illustrative example (and for cases usually encountered) equation 111 may be used since the limits on the first two integrals are greater than 10. This equation further reduces to equation 112, since $c=0$.

$$\int_{t_1}^{t_{24}} R\,dt=\frac{1}{\alpha}\left[\epsilon^{M-L}\left(\frac{1}{L}-\frac{1}{L^2}+\frac{2}{L^3}-\frac{6}{L^4}\right)-\epsilon^{M-N}\left(\frac{1}{N}-\frac{1}{N^2}+\frac{2}{N^3}-\frac{6}{N^4}\right)+\int_{-\infty}^{M-L}\frac{\epsilon^n dn}{n}-\int_{-\infty}^{M-N}\frac{\epsilon^n dn}{n}\right] \qquad (10)$$

With the previously assumed values of α, b, T_0, T_1, and t_1, as in cases 1, 2, and 3a the quantities give

$$\frac{1}{\alpha}=2.5$$

$$D=T_1-T_0=452.905-413.0=39.905$$

$$L=\frac{b}{T_1}=\frac{11{,}500}{452.905}=25.39164$$

$$M=\frac{b}{T_0}=\frac{11{,}500}{413}=27.84504$$

$$N=\frac{b}{T_0+D\epsilon^{-\alpha t}}=\frac{11{,}500}{413+39.905\epsilon^{(-0\cdot 4)(20)}}=27.84413$$

Substituting these values in equation 10 and showing intermediate values to show relative importance of terms yields

$$\int_{t_1}^{t_{24}} R\,dt=2.5[11.628(0.037940)-(1.0009)(0.034707)+6.850+6.425]$$
$$=34.202 \text{ hours cumulative aging from } t_1 \text{ to } t_{24} \qquad (11)$$

Equation 10 contains exponential integrals of the form

$$Ei(x)=\int_{-\infty}^{x}\frac{\epsilon^n}{n}\,dn \qquad (12)$$

These are evaluated by tables in references 6 and 7.

Comparison of Aging for Time-Temperature Cycles: Cases 1, 2, and 3

Summarizing the conditions of this comparison:

Initial temperature $T_0=140$ C (413 K).
Top temperature attained $T_1=180$ C (453 K)(452.905 calculated for cases 3a and 3b).
Elapsed time with heating load $L_1=t_1-t_0=$ 4 hours.
Elapsed time with cooling load $L_0=t_{24}-t_1=$ 20 hours for cases 1 and 3b; 4 hours to T_0+16 hours at T_0 for case 2.
Final temperature at end of 24 hours $=T_0=$ 140 C (413 K)(413.013 for case 3b).
Time constant $=1/\alpha=2.5$.

The cumulative relative aging from combined exponential heating and cooling cycle, case 3 is the sum of equations 8 and 11 = 23.688 + 34.202 = 57.890 hours.

$$\text{Relative aging over 24-hour cycle of Fig. 1}=\frac{57.890}{24}=2.412 \qquad (13)$$

These three cases for the conditions compared gave results as found in Table I.

To have a broader base for comparison, calculations similar to the foregoing were made with elapsed time of heating load L_1 with values from $t_1=1$, to $t_1=20$ (only to $t_1=12$ for the triangular case, since for t_1 greater than 12 the time t_1 to t_{24} would be insufficient to reach T_0 for the cooling portion). Also note that with exponential cooling the temperature at the end of the 24-hour cycle (t_{24}) was 414.36 K with a 15-hour heating cycle, and 423.09 K for 20 hours' heating (it did not return to $T_0=413$ K). The top temperature used in each case was the calculated value obtained with the use of equation 1, (and a rounded off value for cases 1 and 2). These temperature cycles are graphically shown in Fig. 6.

The results of aging calculations for various time-temperature cycles are shown in Table II and in Fig. 7. The percent errors with the use of the approximations of cases 1 and 2 compared to the theoretically correct are shown in Table III.

Application to Aging Problems

In actual aging problems, which involve a variety of parameters, the calculation of results from the theoretical equations will be rather tedious. Some progress has been made in the development of graphical methods based on these equations. It is expected that these graphical simplifications will be available in the not too distant future. Computer programming has been considered and the detailed appendixes allow this to be picked up at the proper place as indicated at the end of each appendix.

Conclusions

1. Equations have been developed giving relative insulation aging for conditions of both a temperature change at a constant rate and temperature change at an exponential rate.

2. These equations incorporate the theo-

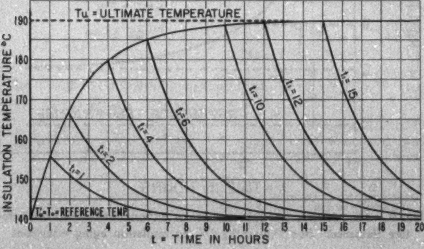

Fig. 6. Insulation temperature cycles used in comparing aging calculations based on various assumptions

retically sound and generally accepted Arrhenius' chemical reaction rate concept applied to insulation deterioration as contrasted to the rough approximation of a "degree rule."

3. Typical examples show that insulation calculations based on the assumption of a triangular temperature cycle, replacing the much more accurate exponential temperature cycle, give answers of the order of 10% too small.

4. Typical examples show that insulation calculations based on the quite common assumption of a rectangular temperature cycle, replacing the much more accurate exponential temperature cycle, give answers that are too small by the order of 5% for short time loads to as much as 30% too large for longer time loads.

5. Calculations based on exponential temperature change as is generally experienced by apparatus can now be more accurately applied in investigating the effect of insulation aging in regard to apparatus time constant, loading practices, insulations with different aging rates, and insulations of different temperature classes.

Appendix I. Nomenclature

$A=T_u-T_0'$, ultimate temperature rise above T_0'; see Fig. 8
$D=T_1-T_0'$, ultimate temperature fall below T_1; see Fig. 9
$L=b/T_1$ (simplifying nomenclature)
$M=b/T_0+c$ (simplifying nomenclature)
$N=b/T_0+c+D\epsilon^{-\alpha t}$ (simplifying nomenclature)
R = relative insulation aging with unity assigned to aging at reference temperature T_0
T = insulation temperature (C+273) at any given time t, K
T_1 = insulation temperature at $t=t_1$ (final temperature for increasing temperature cycle and initial temperature for decreasing temperature cycle), K
T_0' = initial insulation temperature at $t=t_0=0$ for Fig. 8; or $t=\infty$ for Fig. 9, K
T_0 = reference insulation temperature, K. (Normally this would be rated hottest spot temperature for insulation used considering 30 C ambient)
T_u = ultimate maximum temperature of insulation for particular load for $t=\infty$; see Fig. 8, K
$a=T_0$ (used in equations to indicate that this is a reference quantity independent of time)
b = slope of relative aging curve; see references 4 and 5 for representative values)
$c=T_0'-T_0$; see Figs. 5, 8, and 9
d = differential, with adjacent variable
ϵ = base of Naperian logarithms = 2.71828
f = per-hour rate of temperature change, C
$m=b/T_0+c+D\epsilon^{-\alpha t}$ (simplifying nomenclature)
$n=(D\epsilon^{-\alpha t}m)/(T_0-c)$ (simplifying nomenclature)
$p=b/T_0+c$ (simplifying nomenclature)
$r=b/A+T_0+c$ (simplifying nomenclature)
$s=b/T_0+c+A(1-\epsilon^{-\alpha t})$ (simplifying nomenclature)
t = time, hours
t_0 = time at $t=0$
$u=b/T_0+c+ft$ (simplifying nomenclature)
$u_0=b/T_0+c$ (value of u at $t=0$)

$1/\alpha$ = time constant of the apparatus (time to reach 63.2% of T_u)
ln = logarithm to base ϵ

Appendix II. Insulation-Aging Calculation with Constant Rate of Temperature Increase

In this evaluation insulation aging will be computed in terms of relative aging in the manner proposed by Sumner, Stein, and Lockie.[8] This method assigns a factor of unity to the insulation deterioration at some reference temperature. Aging at any other temperature is then some fraction or some multiple of the aging at this specified temperature, depending on whether the temperature is lower or higher than the specified base temperature.

Insulation aging will also be considered to be a function of the chemical reaction rate theory of Arrhenius[9] as suggested by Akahira,[10,11] Malmlow,[12] and Dakin.[3]

Combining these ideas results in the equation

$$\ln R = b\left(\frac{1}{T_0} - \frac{1}{T}\right) \tag{14}$$

Graphs of this equation are given in Fig. 4 with two representative values of b and T_0. Equation 1 may be written

$$R = \epsilon^{\left(\frac{b}{T_0} - \frac{b}{T}\right)} \tag{15}$$

$$= \epsilon^{\left(\frac{b}{T_0}\right)} \epsilon^{-\left(\frac{b}{T}\right)} \tag{16}$$

For the constant rate of temperature increase, Fig. 5 shows the relation between temperature and time. From Fig. 5

$$T_0' = T_0 + c \tag{17}$$

$$T = T_0' + ft \tag{18}$$

Then

$$T = T_0 + c + ft \tag{19}$$

Let

$$a = T_0 \text{ (since } T_0 \text{ is independent of time)} \tag{20}$$

Then

$$T = a + c + ft \tag{21}$$

Substituting equations 20 and 21 in equation 16 yields

$$R = \epsilon^{\left(\frac{b}{a}\right)} \epsilon^{-\left(\frac{b}{a+c+ft}\right)} \tag{22}$$

The cumulative relative aging from time $t=0$ to $t=t$ is $\int_0^t R\,dt$. Then

$$\int_0^t R\,dt = \epsilon^{\left(\frac{b}{a}\right)} \int_0^t \epsilon^{-\left(\frac{b}{a+c+ft}\right)} dt \tag{23}$$

Let

$$u = \frac{b}{a+c+ft} \tag{24}$$

Then

$$du = -\frac{bf}{(a+c+ft)^2}\,dt$$

$$= -\frac{b^2 f}{b(a+c+ft)^2}\,dt \left(\text{multiplying by } \frac{b}{b}\right)$$

$$= -\frac{f}{b}\,u^2 dt \text{ (from equation 24)}$$

Therefore

$$dt = -\frac{b}{f}\frac{du}{u^2} \tag{25}$$

Therefore, substituting equations 24 and 25 in equation 23 yields

$$\int_0^t R\,dt = \epsilon^{\left(\frac{b}{a}\right)} \int_0^t \epsilon^{-u}\left(-\frac{b}{f}\frac{du}{u^2}\right)$$

$$= -\frac{b}{f}\,\epsilon^{\left(\frac{b}{a}\right)} \int_0^t \frac{\epsilon^{-u}}{u^2}\,du \tag{26}$$

The right-hand integral must be integrated by parts. Let

$$\int \frac{\epsilon^{-u}}{u^2}\,du = \int w\,dv \tag{27}$$

By the well-known integration by parts transformation

$$\int w\,dv = wv - \int v\,dw \tag{28}$$

Let

$$w = \epsilon^{-u} \tag{29}$$

Then

$$dw = -\epsilon^{-u}\,du \tag{30}$$

Let

$$dv = \frac{du}{u^2} \tag{31}$$

Then

$$v = \int \frac{du}{u^2} = -\frac{1}{u} \tag{32}$$

Substituting equations 29, 30, 31, and 32 in equation 28 yields

$$\int w\,dv = -\frac{\epsilon^{-u}}{u} - \int \frac{\epsilon^{-u}}{u}\,du \tag{33}$$

Substituting equation 33 in equation 27 yields

$$\int \frac{\epsilon^{-u}}{u^2}\,du = -\frac{\epsilon^{-u}}{u} - \int \frac{\epsilon^{-u}}{u}\,du \tag{34}$$

Substituting equation 34 in equation 26 yields

$$\int_0^t R\,dt = -\frac{b}{f}\,\epsilon^{\left(\frac{b}{a}\right)} \left(-\frac{\epsilon^{-u}}{u} - \int \frac{\epsilon^{-u}}{u}\,du\right)_0^t$$

$$= +\frac{b}{f}\,\epsilon^{\left(\frac{b}{a}\right)} \left(\left.\frac{\epsilon^{-u}}{u}\right|_0^t + \int_0^t \frac{\epsilon^{-u}}{u}\,du\right) \tag{35}$$

Using equation 24 to determine boundary conditions, and noting from equation 20 that $a = T_0$, yields at $t=0$

$$u = \frac{b}{a+c} = \frac{b}{T_0+c} = u_0 \tag{36}$$

and at $t=t$

$$u = \frac{b}{a+c+ft} = \frac{b}{T_0+c+ft} \tag{37}$$

Substituting equations 20, 36, and 37 in equation 35 yields

$$\int_0^t R\,dt = \frac{b}{f}\,\epsilon^{\left(\frac{b}{T_0}\right)} \left(\left.\frac{\epsilon^{-u}}{u}\right|_{u_0}^{u} + \int_{u_0}^{u} \frac{\epsilon^{-u}}{u}\,du\right)$$

$$\int_0^t R\,dt = \frac{b}{f}\,\epsilon^{\left(\frac{b}{T_0}\right)} \left[\left(\frac{\epsilon^{-u}}{u} - \frac{\epsilon^{-u_0}}{u_0}\right) + \int_{u_0}^{u} \frac{\epsilon^{-u}}{u}\,du\right] \tag{38}$$

The right-hand integral can be evaluated by changing into the form of an exponential integral, $-Ei(-x)$, by the following transformation:

$$\int_{u_0}^{u} = \int_{u_0}^{\infty} - \int_{u}^{\infty} \tag{39}$$

Using equation 39 in equation 38 yields

$$\int_0^t R\,dt = \frac{b}{f}\,\epsilon^{\left(\frac{b}{T_0}\right)} \left(\frac{\epsilon^{-u}}{u} - \frac{\epsilon^{-u_0}}{u_0} + \int_{u_0}^{\infty} \frac{\epsilon^{-u}}{u}\,du - \int_{u}^{\infty} \frac{\epsilon^{-u}}{u}\,du\right) \tag{40}$$

Tables of these integrals are available for values of $u = 0$ to 15 in reference 6 and $u = 20$ to 50 in reference 7. However, u and u_0 are usually of the order of 20 to 30 and the reference tables are in rather large increments (also, this reference is not generally available). For values of $u > 10$ the following expression may be used with an error of less than 1.0% (less than 0.05% for $u > 20$):

$$\int_u^{\infty} \frac{\epsilon^{-u}}{u}\,du = \epsilon^{-u}\left(\frac{1}{u} - \frac{1}{u^2} + \frac{2!}{u^3} - \frac{3!}{u^4} + \ldots\right) \tag{41}$$

The difference between the true value of the integral and the sum of a finite number of the terms used is of the order of the last term used.

Substituting equation 41 in equation 40 yields

$$\int_0^t R\,dt = \frac{b}{f}\,\epsilon^{\left(\frac{b}{T_0}\right)} \left[\frac{\epsilon^{-u}}{u} - \frac{\epsilon^{-u_0}}{u_0} + \epsilon^{-u_0}\left(\frac{1}{u_0} - \frac{1}{u_0^2} + \frac{2!}{u_0^3} - \frac{3!}{u_0^4}\right) - \epsilon^{-u}\left(\frac{1}{u} - \frac{1}{u^2} + \frac{2!}{u^3} - \frac{3!}{u^4}\right)\right] \tag{42}$$

This simplifies to

$$\int_0^t R\,dt = \frac{b}{f}\,\epsilon^{\left(\frac{b}{T_0}\right)} \left[\epsilon^{-u}\left(\frac{1}{u^2} - \frac{2}{u^3} + \frac{6}{u^4}\right) - \epsilon^{-u_0}\left(\frac{1}{u_0^2} - \frac{2}{u_0^3} + \frac{6}{u_0^4}\right)\right]$$

$$= \frac{b}{f}\left[\epsilon^{\left(\frac{b}{T_0} - u\right)}\left(\frac{1}{u^2} - \frac{2}{u^3} + \frac{6}{u^4}\right) - \epsilon^{\left(\frac{b}{T_0} - u_0\right)}\left(\frac{1}{u_0^2} - \frac{2}{u_0^3} + \frac{6}{u_0^4}\right)\right] \tag{43}$$

where, from equations 36 and 37,

$$u_0 = \frac{b}{T_0+c} \text{ and } u = \frac{b}{T+c+ft}$$

A frequent case is where $c=0$, meaning that $T_0'=T_0$, in which case note that equation 43 becomes

$$\int_0^t R\,dt=\frac{b}{f}\left[\epsilon^{u_0-u}\left(\frac{1}{u^2}-\frac{2}{u^3}+\frac{6}{u^4}\right)-\epsilon^{u_0-u_0}\left(\frac{1}{u_0^2}-\frac{2}{u_0^3}+\frac{6}{u_0^4}\right)\right]$$

$$=\frac{b}{f}\left[\epsilon^{u_0-u}\left(\frac{1}{u^2}-\frac{2}{u^3}+\frac{6}{u^4}\right)-\left(\frac{1}{u_0^2}-\frac{2}{u_0^3}+\frac{6}{u_0^4}\right)\right] \quad (44)$$

where $u_0=(b/T_0)$; $u=b/(T_0+ft)$; and $c=0$.

For computer programming use equation 40 with infinite series, equation 41. (The number of terms used must not be greater than u.)

Appendix III. Insulation Aging Calculation with Exponential Temperature Increase

Assume an exponential temperature increase in accordance with Fig. 8 with the relation

$$T=T_0'+A(1-\epsilon^{-\alpha t}) \quad (45)$$

If $T_0'=T_0+c$ (see Fig. 8) equation 45 becomes

$$T=T_0+c+A(1-\epsilon^{-\alpha t}) \quad (46)$$

Using relative aging relations as developed in Appendix II, and starting with equation 16 in Appendix II, yields

$$R=\epsilon^{\left(\frac{b}{T_0}\right)}\epsilon^{-\left(\frac{b}{T}\right)} \quad (47)$$

Substituting equation 46 in equation 47 yields

$$R=\epsilon^{\left(\frac{b}{T_0}\right)}\epsilon^{-\left(\frac{b}{T_0+c+A(1-\epsilon^{-\alpha t})}\right)} \quad (48)$$

The cumulative relative aging from time $t=0$ to $t=t$ is $\int_0^t R\,dt$.

$$\int_0^t R\,dt=\epsilon^{\frac{b}{T_0}}\int_0^t \epsilon^{-\frac{b}{T_0+c-A(1-\epsilon^{-\alpha t})}}\,dt \quad (49)$$

Let

$$x=\frac{b}{T_0+c+A(1-\epsilon^{-\alpha t})} \quad (50)$$

Then

$$dx=\frac{-b\alpha A\epsilon^{-\alpha t}}{[T_0+c+A(1-\epsilon^{-\alpha t})]^2}\,dt \quad (51)$$

$$=\frac{-b^2\alpha A\epsilon^{-\alpha t}\,dt}{b[T_0+c+A(1-\epsilon^{-\alpha t})]^2}\,dt$$

(multiplying by b/b).

$$dx=\frac{-\alpha A\epsilon^{-\alpha t}}{b}x^2\,dt \quad (51A)$$

(from 50 and 51). But $T_0+c+A-A\epsilon^{-\alpha t}=b/x$ (from equation 50). Therefore

$$\epsilon^{-\alpha t}=-\frac{\frac{b}{x}-T_0-c}{A}+1 \quad (52)$$

Substituting equation 52 in equation 51(A) yields

$$dx=-\frac{x^2A\alpha}{b}\left[-\frac{\frac{b}{x}-T_0-c}{A}+1\right]dt$$

$$=x\alpha\left[1+x\left(-\frac{A+T_0+c}{b}\right)\right]dt \quad (53)$$

Therefore

$$dt=\frac{dx}{x\alpha\left[1+x\left(-\frac{A+T_0+c}{b}\right)\right]} \quad (54)$$

Let

$$g=-\left(\frac{A+T_0+c}{b}\right) \quad (55)$$

Then

$$dt=\frac{dx}{x\alpha(1+gx)} \quad (56)$$

Substituting equations 50 and 56 in equation 49

$$\int_0^t R\,dt=\frac{\epsilon^{\frac{b}{T_0}}}{\alpha}\int_{x_0}^{x}\frac{\epsilon^{-x}\,dx}{x(1+gx)} \quad (57)$$

Let

$$h=\frac{\epsilon^{\frac{b}{T_0}}}{\alpha} \quad (58)$$

Let

$$\frac{1}{x(1+gx)}=\frac{B}{x}+\frac{E}{1+gx}$$

from which $B=1$ and $E=-g$, resulting in

$$\frac{1}{x(1+gx)}=\frac{1}{x}-\frac{g}{1+gx} \quad (59)$$

Substituting equations 58 and 59 in equation 57

$$\int_0^t R\,dt=h\int_{x_0}^{x}\epsilon^{-x}\left[\frac{1}{x}-\frac{g}{1+gx}\right]dx$$

$$=h\int_{x_0}^{x}\frac{\epsilon^{-x}}{x}\,dx-h\int_{x_0}^{x}\frac{g\epsilon^{-x}}{1+gx}\,dx \quad (60)$$

Let

$$F=-h\int_{x_0}^{x}\frac{g\epsilon^{-x}}{1+gx}\,dx \quad (61)$$

Also let

$$z=1+gx \quad (62)$$

Then

$$dz=g\,dx$$

$$dx=\frac{dz}{g}$$

$$x=\frac{z-1}{g}$$

from equation 62.

Make these substitutions in equation 61. Then

$$F=-h\int_{z_0}^{z}\frac{g\epsilon^{-\frac{z-1}{g}}}{z}\frac{dz}{g} \quad (63)$$

$$=-h\epsilon^{\frac{1}{g}}\int_{z_0}^{z}\frac{\epsilon^{-\frac{z}{g}}}{z}\,dz \quad (64)$$

Let

$$y=\frac{z}{g} \quad (65)$$

Then

$$dy=\frac{dz}{g}$$

$$dz=g\,dy$$

from equation 65.

$$z=gy$$

Substituting equation 65 in equation 64 yields

$$F=-h\epsilon^{\frac{1}{g}}\int_{y_0}^{y}\frac{\epsilon^{-y}}{gy}\,g\,dy$$

$$=-h\epsilon^{\frac{1}{g}}\int_{y_0}^{y}\frac{\epsilon^{-y}}{y}\,dy \quad (66)$$

Substituting equation 66 in equation 61, then equation 61 in equation 60 yields

$$\int_0^t R\,dt=h\int_{x_0}^{x}\frac{\epsilon^{-x}}{x}\,dx-h\epsilon^{\frac{1}{g}}\int_{y_0}^{y}\frac{\epsilon^{-y}}{y}\,dy \quad (67)$$

Evaluating limits on the first integral of equation 67, when $t=0$, yields

$$x=\frac{b}{T_0+c}=x_0 \quad (68)$$

from equation 50. When $t=t$

$$x=\frac{b}{T_0+c+A(1-\epsilon^{-\alpha t})} \quad (69)$$

from equation 50.

Evaluating limits on the second integral of equation 67 yields

$$y=\frac{z}{g}$$

from equation 65;

$$=\frac{1+gx}{g}$$

from equation 62;

$$=\frac{1}{g}+x$$

$$=-\frac{b}{A+T_0+c}+\frac{b}{T_0+c+A(1-\epsilon^{-\alpha t})}$$

from equations 50 and 55.

When $t=0$

$$y=-\frac{b}{A+T_0+c}+\frac{b}{T_0+c}=y_0 \quad (70)$$

When $t=t$

$$y=-\frac{b}{A+T_0+c}+\frac{b}{T_0+c+A(1-\epsilon^{-\alpha t})} \quad (71)$$

Substitute limits given, equations 68 through 71, in equation 67, and note that

$$h=\frac{\epsilon^{\frac{b}{T_0}}}{\alpha}$$

from equation 58, and that

$$\epsilon^{\frac{1}{\theta}}=\epsilon^{-\frac{b}{A+T_0+c}}$$

from equation 55, yielding

$$\int_0^t Rdt=\frac{\epsilon^{\frac{b}{T_0}}}{\alpha}\left[\int_{\frac{b}{T_0+c}}^{\frac{b}{T_0+c+A(1-\epsilon^{-\alpha t})}} \times \frac{\epsilon^{-x}}{x}\,dx-\epsilon^{-\frac{b}{A+c+T_0}}\times \int_{-\frac{b}{A+c+T_0}+\frac{b}{T_0+c}}^{-\frac{b}{A+c+T_0}+\frac{b}{T_0+c+A(1-\epsilon^{-\alpha t})}} \frac{\epsilon^{-y}}{y}dy\right] \quad (72)$$

To simplify nomenclature, let

$$p=\frac{b}{T_0+c} \quad (73)$$

$$r=\frac{b}{A+T_0+c} \quad (74)$$

$$s=\frac{b}{T_0+c+A(1-\epsilon^{-\alpha t})} \quad (75)$$

Then equation 72 becomes

$$\int_0^t Rdt=\frac{\epsilon^{\frac{b}{T_0}}}{\alpha}\left[\int_p^s\frac{\epsilon^{-x}}{x}\,dx-\epsilon^{-r}\times \int_{-r+p}^{-r+s}\frac{\epsilon^{-y}}{y}dy\right] \quad (76)$$

The integrals in equation 76 may be put in the form of $[-Ei(-x)]$ functions (exponential integrals)[8] by using the following relations:

$$\int_{x_0}^x\frac{\epsilon^{-x}}{x}\,dx=\underset{a\to\infty}{\text{limit}}\left[\int_{x_0}^a\frac{\epsilon^{-x}}{x}\,dx+\int_a^x\frac{\epsilon^{-x}}{x}\,dx\right]$$

$$=\int_{x_0}^\infty\frac{\epsilon^{-x}}{x}\,dx+\int_\infty^x\frac{\epsilon^{-x}}{x}\,dx$$

$$\int_{x_0}^x\frac{\epsilon^{-x}}{x}\,dx=\int_{x_0}^\infty\frac{\epsilon^{-x}}{x}\,dx-\int_x^\infty\frac{\epsilon^{-x}}{x}\,dx \quad (77)$$

Using equation 77 in equation 76 yields

$$\int_0^t Rdt=\frac{\epsilon^{\frac{b}{T_0}}}{\alpha}\left[\int_p^\infty\frac{\epsilon^{-x}}{x}\,dx-\int_s^\infty\frac{\epsilon^{-x}}{x}\,dx-\epsilon^{-r}\left(\int_{p-r}^\infty\frac{\epsilon^{-y}}{y}\,dy-\int_{s-r}^\infty\frac{\epsilon^{-y}}{y}\,dy\right)\right] \quad (78)$$

Equation 78 is in the form of $[-Ei(-x)]$ functions and can thus be evaluated by reference to tables of exponential integrals.[6,7]

Since the values of p and s in equation 78 are usually greater than 20, and since tables of the $[-Ei(-x)]$ functions are in large increments, or in some cases not available, use is made of equation 41 to replace the first two integrals of equation 78. Equation 78 then becomes

$$\int_0^t Rdt=\frac{\epsilon^{\frac{b}{T_0}}}{\alpha}\left[\epsilon^{-p}\left(\frac{1}{p}-\frac{1}{p^2}+\frac{2}{p^3}-\frac{6}{p^4}\right)-\epsilon^{-s}\left(\frac{1}{s}-\frac{1}{s^2}+\frac{2}{s^3}-\frac{6}{s^4}\right)-\epsilon^{-r}\left(\int_{p-r}^\infty\frac{\epsilon^{-y}}{y}\,dy-\int_{s-r}^\infty\frac{\epsilon^{-y}}{y}\,dy\right)\right] \quad (79)$$

For the case of $T_0'=T$ $(c=0)$, $b/T_0=p$. Hence

$$\int_0^t Rdt=\frac{\epsilon^p}{\alpha}\left[\epsilon^{-p}\left(\frac{1}{p}-\frac{1}{p^2}+\frac{2}{p^3}-\frac{6}{p^4}\right)-\epsilon^{-s}\left(\frac{1}{s}-\frac{1}{s^2}+\frac{2}{s^3}-\frac{6}{s^4}\right)-\epsilon^{-r}\left(\int_{p-r}^\infty\frac{\epsilon^{-y}}{y}\,dy-\int_{s-r}^\infty\frac{\epsilon^{-y}}{y}\,dy\right)\right]$$

$$\int_0^t Rdt=\frac{1}{\alpha}\left[1\left(\frac{1}{p}-\frac{1}{p^2}+\frac{2}{p^3}-\frac{6}{p^4}\right)-\epsilon^{p-s}\left(\frac{1}{s}-\frac{1}{s^2}+\frac{2}{s^3}-\frac{6}{s^4}\right)-\epsilon^{p-r}\left(\int_{p-r}^\infty\frac{\epsilon^{-y}}{y}dy-\int_{s-r}^\infty\frac{\epsilon^{-y}}{y}\,dy\right)\right] \quad (80)$$

Caution: Use equation 80 only if $T_0'=T_0$; otherwise use equation 79.

Note that $\int_z^\infty\frac{\epsilon^{-y}}{y}\,dy$ in equations 79 and 80 are in the form of exponential integrals which may be evaluated by tables.[6,7] For computer programming use equation 78 with infinite series 41. (The number of terms used must not be greater than u.)

Appendix IV. Insulation-Aging Calculation with Exponential Temperature Decrease

Assume an exponential temperature decrease in accordance with Fig. 9, with the relation

$$T=T_1-D(1-\epsilon^{-\alpha t})$$
$$=T_0'+De^{-\alpha t}$$
$$=T_0+c+De^{-\alpha t} \quad (81)$$

Using relative aging relations as developed in Appendix II, and starting with equation 16 yields

$$R=\epsilon^{\frac{b}{T_0}}\ \epsilon^{-\frac{b}{T}} \quad (82)$$

Substituting equation 81 in equation 82 yields

$$R=\epsilon^{\frac{b}{T_0}}\ \epsilon^{-\frac{b}{T_0+c+De^{-\alpha t}}} \quad (83)$$

The cumulative relative aging from time $t=0$ to $t=t$ is $\int_0^t Rdt$.

$$\int_0^t Rdt=\epsilon^{\frac{b}{T_0}}\int_0^t\epsilon^{-\frac{b}{T_0+c+De^{-\alpha t}}}dt \quad (84)$$

Let

$$m=\frac{b}{T_0+c+D\epsilon^{-\alpha t}} \quad (85)$$

Then

$$\epsilon^{-\alpha t}=\frac{b}{mD}-\frac{T_0+c}{D} \quad (86)$$

Differentiating,

$$-\alpha\epsilon^{-\alpha t}\,dt=-\frac{bD}{(mD)^2}\,dm$$

$$dt=\frac{b}{m^2D\alpha\epsilon^{-\alpha t}}\,dm \quad (87)$$

Substituting equation 86 in 87 yields

$$dt=\frac{b\,dm}{m^2D\alpha\left(\frac{b}{mD}-\frac{T_0+c}{D}\right)}$$

$$=\frac{dm}{\alpha m\left[1-m\frac{(T_0+c)}{b}\right]} \quad (88)$$

Let

$$k=\frac{T_0+c}{b} \quad (89)$$

Substituting equation 89 in 88 yields

$$dt=-\frac{dm}{\alpha m(1-km)} \quad (90)$$

Substituting equations 85 and 90 in equation 84 yields

$$\int_0^t Rdt=\epsilon^{\frac{b}{T_0}}\int_{m_0}^m\epsilon^{-m}\frac{dm}{\alpha m(1-km)}$$

$$=\frac{\epsilon^{\frac{b}{T_0}}}{\alpha}\int_{m_0}^m\epsilon^{-m}\frac{dm}{m(1-km)} \quad (91)$$

Let

$$\frac{1}{m(1-km)}=\frac{G}{m}+\frac{H}{1-km}$$

from which $G=1$ and $H=k$, resulting in

$$\frac{1}{m(1-km)}=\frac{1}{m}+\frac{k}{1-km} \quad (92)$$

Substituting equation 92 in 91 yields

$$\int_0^t Rdt=\frac{\epsilon^{\frac{b}{T_0}}}{\alpha}\left[\int_{m_0}^m\epsilon^{-m}\,dm\left(\frac{1}{m}+\frac{k}{1-km}\right)\right]$$

$$=\frac{\epsilon^{\frac{b}{T_0}}}{\alpha}\left[\int_{m_0}^m\epsilon^{-m}\frac{dm}{m}+\int_{m_0}^m\frac{k\epsilon^{-m}dm}{1-km}\right] \quad (93)$$

Let

$$J=\int_{m_0}^m\frac{k\epsilon^{-m}dm}{1-km} \quad (94)$$

Let

$$kn=1-km$$

$$n=\frac{1}{k}-m \quad (95)$$

$$m=\frac{1}{k}-n \qquad (96)$$

$$dm=-dn \qquad (97)$$

Substituting equations 95 through 97 in equation 94

$$J=\int_{n_0}^{n}\frac{k\epsilon^{-\left(\frac{1}{k}-n\right)}(-dn)}{kn}$$

$$=-\epsilon^{-\frac{1}{k}}\int_{n_0}^{n}\frac{\epsilon^{n}}{n}dn \qquad (98)$$

Substituting equation 98 in equations 93 and 94

$$\int_0^t Rdt=\frac{\epsilon^{-\frac{b}{T_0}}}{\alpha}\left[\int_{m_0}^{m}\frac{\epsilon^{-m}}{m}dm-\epsilon^{-\frac{1}{k}}\times \int_{n_0}^{n}\frac{\epsilon^{n}}{n}dn\right] \qquad (99)$$

Evaluating limits on the first integral of equation 99 from equation 85, when $t=0$,

$$m=\frac{b}{T_0+c+D}=\frac{b}{T_1}=m_0 \qquad (100)$$

and when $t=t$

$$m=\frac{b}{T_0+c+D\epsilon^{-\alpha t}} \qquad (101)$$

Evaluating limits on the second integral of equation 99 from equation 95

$$n=\frac{1}{k}-m$$

Substituting in this equations 85 and 89, when $t=t$,

$$n=\frac{b}{T_0+c}-\frac{b}{T_0+c+D\epsilon^{-\alpha t}} \qquad (102)$$

and when $t=0$,

$$n_0=\frac{b}{T_0+c}-\frac{b}{T_1} \qquad (103)$$

where $T_1=T_0+c+D$

Substituting equations 89 and 100 through 103 in equation 99 yields

$$\int_0^t Rdt=\frac{\epsilon^{\frac{b}{T}}}{\alpha}\left[\int_{\frac{b}{T_1}}^{\frac{b}{T_0+c+D\epsilon^{-\alpha t}}}\frac{\epsilon^{-m}}{m}dm-\epsilon^{-\frac{b}{T_0+c}}\int_{\frac{b}{T_0+c}-\frac{b}{T_1}}^{\frac{b}{T_0+c}-\frac{b}{T_0+c+D\epsilon^{-\alpha t}}}\frac{\epsilon^{n}}{n}dn\right] \qquad (104)$$

Let

$$L=\frac{b}{T_1} \qquad (105)$$

$$M=\frac{b}{T_0+c} \qquad (106)$$

$$N=\frac{b}{T_0+c+D\epsilon^{-\alpha t}} \qquad (107)$$

Substituting equations 105 through 107 in equation 104 yields

$$\int_0^t Rdt=\frac{\epsilon^{\frac{b}{T_0}}}{\alpha}\left[\int_L^N\frac{\epsilon^{-m}}{m}dm-\epsilon^{-M}\int_{M-L}^{M-N}\frac{\epsilon^{n}}{n}dn\right] \qquad (108)$$

The first integral in equation 108 may be put in the form of $(-Ei)(-X)$ functions (exponential integrals) by the use of the relation in equation 77.

Also the second integral in equation 108 may be put in the form of $(+Ei)(+X)$ functions (exponential integrals) by use of the following relation:

$$\int_{x_0}^{x}\frac{\epsilon^{x}}{x}dx=\lim_{a\to-\infty}\left[\int_{x_0}^{a}\frac{\epsilon^{x}}{x}dx+\int_a^x\frac{\epsilon^{x}}{x}dx\right]$$

$$=\int_{x_0}^{-\infty}\frac{\epsilon^{x}}{x}dx+\int_{-\infty}^{x}\frac{\epsilon^{x}}{x}dx$$

$$=-\int_{-\infty}^{x_0}\frac{\epsilon^{x}}{x}dx+\int_{-\infty}^{x}\frac{\epsilon^{x}}{x}dx \qquad (109)$$

Substituting equations 77 and 109 in equation 108 yields

$$\int_0^t Rdt=\frac{\epsilon^{\frac{b}{T_0}}}{\alpha}\left[\int_L^\infty\frac{\epsilon^{-m}}{m}dm-\int_N^\infty\frac{\epsilon^{-m}}{m}dm-\epsilon^{-M}\left(-\int_{-\infty}^{M-L}\frac{\epsilon^{n}}{n}dn+\int_{-\infty}^{M-N}\frac{\epsilon^{n}}{n}dn\right)\right] \qquad (110)$$

If L and N are greater than 10, equation 41 can be used to replace the first two integrals in equation 110 with an error of less than 1.0%. Equation 110 becomes

$$\int_0^t Rdt=\frac{\epsilon^{\frac{b}{T_0}}}{\alpha}\left[e^{-L}\left(\frac{1}{L}-\frac{1}{L^2}+\frac{2}{L^3}-\frac{6}{L^4}\right)-\epsilon^{-N}\left(\frac{1}{N}-\frac{1}{N^2}+\frac{2}{N^3}-\frac{6}{N^4}\right)-\epsilon^{-M}\left(-\int_{-\infty}^{M-L}\frac{\epsilon^{n}}{n}dn+\int_{-\infty}^{M-N}\frac{\epsilon^{n}}{n}dn\right)\right] \qquad (111)$$

For the case of $T_0'=T_0$ (i.e., $c=0$), $b/T_0=M$. Hence

$$\int_0^t Rdt=\frac{\epsilon^{M}}{\alpha}\left[\epsilon^{-L}\left(\frac{1}{L}-\frac{1}{L^2}+\frac{2}{L^3}-\frac{6}{L^4}\right)-\epsilon^{-N}\left(\frac{1}{N}-\frac{1}{N^2}+\frac{2}{N^3}-\frac{6}{N^4}\right)-\epsilon^{-M}\left\{-\int_{-\infty}^{M-L}\frac{\epsilon^{n}}{n}dn+\int_{-\infty}^{M-N}\frac{\epsilon^{n}}{n}dn\right\}\right]$$

$$=\frac{1}{\alpha}\left[\epsilon^{M-L}\left(\frac{1}{L}-\frac{1}{L^2}+\frac{2}{L^3}-\frac{6}{L^4}\right)-e^{M-N}\left(\frac{1}{N}-\frac{1}{N^2}+\frac{2}{N^3}-\frac{6}{N^4}\right)+\int_{-\infty}^{M-L}\frac{\epsilon^{n}}{n}dn-\int_{-\infty}^{M-N}\frac{\epsilon^{n}}{n}dn\right] \qquad (112)$$

Caution: Use equation 112 only if $T_0'=T$ (when $c=0$); otherwise use equation 111. Note that

$$\int_{-\infty}^{x}\frac{\epsilon^{n}}{n}dn$$

in equations 111 and 112, is an exponential integral which can be evaluated from tables.[6,7]

For computer programming use equation 110 with infinite series, equation 41, for the $(-Ei)(-X)$ functions and a series like that of equation 41, except that all signs are made positive for the $(+Ei)(+X)$ functions. (The number of terms used must not be greater than u.)

Discussion

F. H. Buller (Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.): The authors do the industry a service in contribution to the theory of insulation aging. While their fundamental idea appears to be sound, it would seem that the usefulness of their analysis could be extended

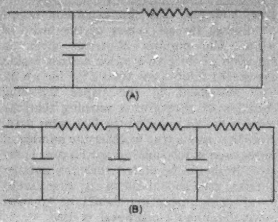

Fig. 10. Types of thermal circuits

A—For simple apparatus; see equation 45
B—For more complicated apparatus

if equation 45 were modified to represent more exactly the types of apparatus encountered in practice. This equation as it stands applies strictly speaking to the type of thermal circuit shown in Fig. 10(A).

The corresponding apparatus could be a bare conductor suspended in air, if the surface thermal resistivity of the conductor or its reciprocal (the coefficient of heat transfer) were constant over the portion of the transient under consideration.

For more complicated apparatus a more elaborate thermal circuit is needed, e.g., see Fig. 10(B). The corresponding equation is

$$T-T_0=A(1-\epsilon^{-\alpha t})+B(1-\epsilon^{-\beta t})+C(1-\epsilon^{-\gamma t})$$

The equation requires one term for each thermal capacitance in the "ladder network" as shown.

This type of circuit has been used successfully to represent an insulated cable in air, with a constant surface thermal resistivity.[1]

A generator, a motor, or a transformer can also be represented by a ladder network similar to that of Fig. 10(B), although it is possible that more meshes might be required; moreover, the approximation is not quite as good unless one or more of the meshes of the ladder network are replaced by suitable subsidiary networks. It is apparent that the corresponding equation can become quite complicated and may even require a computer for its solution.

A cable with very heavy insulation can be treated thermally as a transmission line with suitably distributed constants. In this case the foregoing equation would involve an infinite number of terms of which only the first three or four are usually of practical significance.[2]

The first term of the series is the principal term and it persists for the longest period of time; the other terms serve to modify the transient during its earlier stages. This is not necessarily true in the case of the finite series which represents a generator, a motor, or a transformer; here the various terms may or may not be of the same order of duration depending on circumstances.

Approximations of this sort could possibly be incorporated in the authors' analysis, and since in practically all of this thermal work the superposition principle holds, it might be possible to prepare term-by-term solutions.

Andrew A. Halacsy (Federal Pacific Electric Company, Newark, N. J.): In connection with insulation aging we know rather more about the load than about the temperature in a given period. In practical cases, the authors' method requires the knowledge of the heating and cooling curves of the particular device at the particular load. Only by such curves can the aging be properly calculated. This is true especially because both the knowledge of the temperatures actually reached during a temperature cycle and the knowledge of T_u=ultimate maximum temperature of the insulation for the particular load are required for accurate calculation. This T_u temperature is not reached during the cycling in question nor even in a test with a heavy overload applicable, of course, only for a very short time.

This situation is unfortunate but it seems inevitable because the authors give ample proof that other simplifying methods result in unacceptable error. It must be added that, due to proximity effects in the rather complex heat transmission system of an electric apparatus, the upper part of the heating curve hardly follows an exponential curve. Therefore I suggest using a value for T_u projected from readings not higher than T_1, even if T_u can be measured by test.

An electric apparatus usually has a most dangerous spot in its insulation system, as far as aging is concerned. It is important to know which part of the insulation ages fastest under certain load conditions, because the life of the device in which we are ultimately interested is determined by the life of this particular insulation. This is the very foundation of the concept of the functional evaluation of insulation, well accepted by now. It follows that, if the authors' calculation of insulation aging is carried out for a particular material at the most dangerous or "most aging" spot, and if a load-temperature curve with a projected T_u for that material in that device under that particular load is used in the calculation, the result is an indication of the aging of the whole device. This means that in carrying through calculations of aging it is important to know not so much the evasive hot spot, but rather the most aging spot of the apparatus which might differ from the absolute hot spot, especially if insulating materials with different characteristics are used. This is sanctioned, and rightly, by the recent revision of insulation standards.

The authors are to be congratulated on their mathematics. Unfortunately, they repeatedly hit an evasive exponential integral starting in equations 33 and 67. It is recommended that these should be evaluated by reference to published tables of such integrals. Such a procedure is cumbersome, especially if the proper tables are not available, and I recommend verification, and possibly the use of equation 307 from Burlington's *Handbook*,[1] which reads as follows:

$$\frac{\epsilon^{ax}}{x}\,ax=\log x+ax+\frac{(ax)^2}{2.2!}+\frac{(ax)^3}{3.3!}+\ldots$$

In case of $a=-1$, as in this paper,

$$\frac{\epsilon^{-x}}{x}\,ax=\log x-x+\frac{x^2}{2.2!}-\frac{x^2}{3.3!}+\ldots$$

This is similar to the expansions used by the authors in other places.

Finally, I welcome the special nomenclature in the form of an appendix, and I would strongly recommend this practice in future papers.

L. Meyerhoff (General Cable Corporation, Bayonne, N. J.): Equation 41

$$\int_u^\infty \frac{\epsilon^{-u}}{u}\,du=\epsilon^{-u}\left(\frac{1}{u}-\frac{1}{u^2}+\frac{2!}{u^3}-\frac{3!}{u^4}+\ldots\right)$$

is stated to be a close approximation to the true value of the integral for values of u greater than 10.

The equation as shown is an infinite series which converges for a finite number of terms and then diverges. Thus, if we designate the number of terms by n, the series converges up to $n=u$ but diverges for all values of $n>u$. In other words, if the summation is carried to $n=\infty$ the sum is ∞.

It is perhaps true that if the summation is carried out for only a very limited and prescribed number of terms, such as $n=3$ or $n=u/2$, the approximation is close enough for practical purposes. In equations 42 and 43 only four terms of the series are used and it is perhaps intended never to use more than four terms. However, the last sentence of Appendix III leaves this in doubt. This says: "For computer programming use equation 78 with infinite series 41." It appears important for the authors to clarify the limitations of use of the approximate equation.

L. C. Whitman and **W. W. Whitman:** Mr. Buller has correctly pointed out that equation 45 is an approximation, as was also indicated in references 1 and 2 of the paper. Mr. Buller's additional terms give the added refinement to agree more exactly with a particular thermal circuit. At present, these additional refinements may not be justified in transformer aging calculations. An exception to this may be the case where the load on a liquid-filled unit is suddenly decreased. The thermal gradient from winding to liquid will then fall rapidly until the winding temperature approaches the liquid temperature. The time constant for this portion of the cooling cycle will thus be much different from the remainder of the cycle and could be advantageously expressed as a separate exponential. In the case of a cable with heavy insulation, additional terms are undoubtedly of practical significance.

Inclusion of these additional exponentials in the aging calculations would mean applying the same final equations such as 79 and 111 with the values of the various exponentials substituted and the results summed.

Dr. Halacsy is quite correct in that the hottest spot of equipment may not be the most dangerous spot because it may not be the spot subjected to the highest voltage or mechanical stresses, and because with the use of composite insulations of different temperature endurance, some other lower temperature spot may develop weakness before the actual hottest spot occurs. Thus we must critically examine the particular structure and determine as well as we can the most dangerously aged spot and apply our analysis to this material and region. Mr. Buller has pointed out the apparatus may not strictly follow an exponential curve. Thus, we may find, as Dr. Halacsy suggests, that altering the actual T_u (or even the T_1) used in the equations will give a better approximation of the temperature cycle, particularly if only one exponential is used.

The expansion given by Dr. Halacsy for the evaluation of the exponential integral has the disadvantage that it converges quite slowly for values of u greater than 5. Of course if a computer is used this presents no difficulties. As a further alternative we would suggest the reference at 1 of this closure as an available and inexpensive source of published tables of the exponential integral.

Mr. Meyerhoff has brought out a most important point. Several references give equation 41 as a proper expansion. It is true, however, that this expansion begins to diverge for all values of the order of $n \geq u$. The number of terms given in equation 41 do give a value correct within the stated limits (less than 1%) for $u>10$. The statement in the paper following equation 41 does give a warning that the error is of the order of the last term used. Note that this is true whether the number of terms used is too small or too large. However, it should be stated that the number of terms used should not in any case exceed $n=u$. This restriction should be imposed especially when a computer is used.

A Theoretical Analysis of the Effects of an Electric Field on the Charging of Fine Particles

ARTHUR T. MURPHY
ASSOCIATE MEMBER AIEE

FELIX T. ADLER
NONMEMBER AIEE

GAYLORD W. PENNEY
FELLOW AIEE

Synopsis: Recent measurements of charge imparted to fine particles by unipolar ions in a strong electric field have shown that this charge is appreciably higher than that predicted by previous theoretical analyses. The charge acquired by fine particles is due primarily to ions which strike the particle by virtue of their random heat motion. Previous analyses have assumed that the only field existing was that due to the charge on the particles, thus neglecting any external field which would be present in a corona discharge. Two effects of an external field which influence charging are critically examined: 1. Ions or electrons which travel in the direction of the external field toward the particle will acquire energy in addition to their heat energy. Their increase in energy will allow these elementary particles to overcome more readily the potential field of the charged particle. This effect is shown to be small for molecular ions at atmospheric pressure except for only the very smallest particles but, for charging by free electrons, which have a much longer mean free path, the effect could cause a large increase in charge. 2. The presence of an external field will alter the density distribution of ions around the charged particle since this field opposes the particle field on one side of the particle and aids it on the other side. The general equation for the ion density distribution was not able to be solved. However, approximate finite difference methods using computing machinery show that this effect is important and may almost completely account for the higher charge found with molecular ion charging.

THE CHARGING of particles by ions in a corona discharge has received erratic attention since 1923.[1–4] This work was reviewed and amplified by White[5] in 1951. Recent measurements[6,7] of the charge gained by fine particles in the presence of the strong electric fields which normally exist in a corona discharge have shown that the charge is appreciably higher than that given by the previous theoretical treatments. The discrepancy may be seen in Fig. 1 where the experimental results of Penney and Lynch are compared with the results of the theory given by Arendt and Kallmann, and by White.

The charging of fine particles is attributed almost completely to ions which strike the particle due to their random motion rather those which strike the particle due to their regular motion along the electric field lines. White has differentiated between these two charging mechanisms by calling the first "ion diffusion" or "random-motion" charging, and the latter "field" or "ion-bombardment" charging. An inspection of the previous theoretical treatments of diffusion charging[3,5] shows that the only field assumed existing in the neighborhood of the particle is that due to the charge on the particle. In normal usage, the field in the charging chamber of an electrostatic precipitator is comparable to the field at the surface of the particle due to the charge on the particle.

The purpose of this work is to determine the manner and magnitude of the effect of this external electric field on the random-motion particle-charging process. It will be shown that this field will have two main effects: 1. the effect on the energy of ions traveling toward the particle, and 2. the effect on the density distribution of ions in the neighborhood of the particle.

This paper, after presenting the general theory, will deal primarily with the results and not the details of the various methods used. This is because the methods are somewhat involved and a reasonable explanation would result in undue length. The reader who is interested in a more complete explanation of any part is referred to Murphy's thesis.[8] A brief listing of assumptions made throughout is given in the Appendix and also discussed more completely in reference 8.

General Approach to Determination of Particle Charge

The manner of treating the flow to the particle will follow lines which are closely

Paper 59-102, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted June 23, 1958; made available for printing December 17, 1958.

Arthur T. Murphy is with the University of Wichita, Wichita, Kans., and Felix T. Adler and Gaylord W. Penney are with the Carnegie Institute of Technology, Pittsburgh Pa.

This investigation was supported in part by an Aerotec-Thermix Fellowship and in part by the National Science Foundation. The work was done in part by Arthur T. Murphy in partial fulfillment of the requirements for the degree of Doctor of Philosophy at Carnegie Institute of Technology. The authors wish to acknowledge the Mellon National Bank and Westinghouse Electric Corporation for their generous assistance in extending the use of their computing facilities.

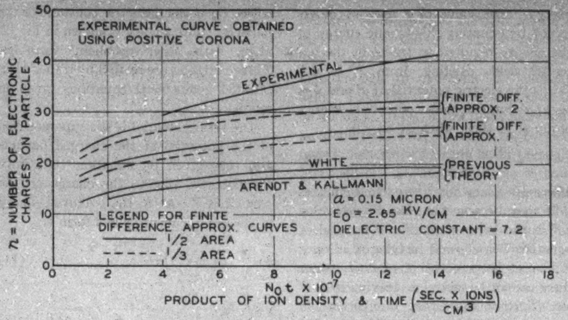

Fig. 1. Comparison of experimentally determined particle charge with previous theories and results of approximate ion density investigation

related to the treatment of diffusion in the kinetic theory.[9,10] A particle, introduced into a region of unipolar ions, of arbitrary density distribution with arbitrary electric fields present, will acquire charge due to ions which strike the particle. Once the particle is charged to some degree, the repelling action of this charge will cause a redistribution of ions in the immediate vicinity of the particle. The new density distribution of ions is then a function of the field of the particle superimposed on the previously existing fields.

An ion in space, heading for the particle, experiences a repelling force from the like-charged sphere. If the ion has a high enough velocity, it may still reach the particle over this repelling force. The number of ions which may do so is dependent on the number of ions which are at any point headed in the correct direction, with sufficient velocity, and which manage to avoid a collision with a molecule on their itinerary. All points in space must be considered, as well as all possible regions on the particle which ions may strike. Obviously, the further an ion must travel to reach the sphere, the less likely it is to avoid hitting a molecule. The counterbalancing of these effects is considered in the following mathematical treatment.

To determine the number of ions arriving at the entire particle surface per unit time, the rate of arrival of ions on an infinitesimal area dS in a general position on the sphere will first be considered (see Fig. 2), then an integration over the particle surface will give the desired result. The rate at which ions arrive at dS will be found by considering the number of ions which reach dS from an infinitesimal volume dV at a general point in space P, after having had a collision with a molecule at P. Then, an integration over all space that can "see" the area dS will yield the total rate of flow to dS. The expression "the volume dV at the point P" will be shortened to "the point P" in the following discussion.

Care must be taken that ions which may reach the particle are counted only once. This is guaranteed by the collision-type accounting. The only ions which are in dV and headed toward dS which are counted in the calculation will be those which have just had a collision in dV. Others which may be passing through P heading towards dS will be counted when P is further out (on the radius vector r) at the point where they had their last collision.

On the basis of the assumptions, the number of ions which have a collision at P per unit time with a speed between c and $c+dc$ after collision is

$$N\frac{c}{\lambda}\, f(c)dc\,dV \qquad (1)$$

where $f(c)$ is the distribution of speeds without regard to direction, i.e., $f(c)dc$ is the probability that an ion will have a speed between c and $c+dc$ after collision; N is the number of ions per unit volume at P. Of this number, the fraction $dS \cos\theta_r/4\pi r^2$ is heading in solid angle which dS makes with the point P if it is assumed that the scattering after collision is isotropic. Therefore, the number is

$$N\frac{c}{\lambda} f(c)dc\,\frac{dS\cos\theta_r}{4\pi r^2}\,dV \qquad (2)$$

ions per unit time with speeds between c and $c+dc$ leave P, after a collision, headed for dS.

Now, consider that only a fraction of those that leave P for dS will actually reach the area because: 1. there is a possibility that they may have a collision with a molecule before traveling the the distance r (and therefore should not be counted here, even if they eventually reach dS, since only those ions are being counted which reach dS after having had their last collision at P), and 2. the speed c may not be great enough to overcome the potential field due to the charge already on the particle.

Accordingly the result in expression 2 must be multiplied by the probability of not hitting a molecule in the distance r, i.e., $e^{-r/\lambda}$. Also, to count only those ions with velocity in the range such that they may reach the particle, it is necessary to integrate over all speeds above a certain minimum c_m, which is the speed an ion would need at P to just reach dS with zero velocity in the presence of the existing potential fields.

Hence, we now have the rate of arrival of ions at dS from P and if 100% attachment is assumed, this is also equal to the rate of increase of ions on the particle which have traveled from P to dS.

$$\left.\frac{dn}{dt}\right|_{P-dS} = N\,dV\,\frac{dS\cos\theta_r}{4\pi r^2}\,e^{-r/\lambda}\int_{c_m}^{\infty}\frac{c}{\lambda}\,f(c)dc \qquad (3)$$

An integration over all points that can be "seen" by dS gives with
$dV = r^2 \sin\theta_r d\theta_r d\phi_r dr$

r goes from 0 to ∞
θ_r goes from 0 to $\pi/2$
ϕ_r goes from 0 to 2π

$$\left.\frac{dn}{dt}\right|_{dS} = \frac{dS}{4\pi}\int_0^{\infty} dr \int_0^{\pi/2} d\theta_r \sin\theta_r \times$$
$$\int_0^{2\pi} d\phi_r\, N\cos\theta_r\, e^{-r/\lambda}\int_{c_m}^{\infty} c/\lambda\, f(c)dc \qquad (4)$$

where c_m is a function of position.

The form of equation 4 is such that it applies to any area dS on the sphere if the

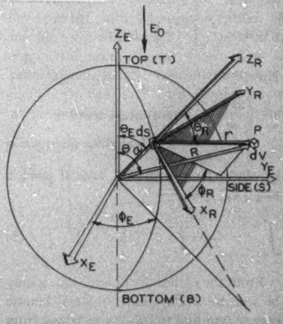

Fig. 2. Co-ordinate system for ion at point P in volume dV heading for area dS on sphere

quantities N and c_m are expressed in general form. The determination of the forms of the velocity (or energy) integral and N for the special case of a uniform external field will now be considered. The total charging rate may then be obtained by allowing dS to take on all values over the particle.

Energy Distribution of Ions

In the nonequilibrium situation of the ions in a force field, it is known that the velocity distribution function will deviate from that for an equilibrium situation i.e., the distribution function will not be exactly Maxwellian.[11] No general velocity distribution function for ions in a field exists in the literature. However, the distribution of velocities desired in equation 4 is the distribution of velocities just after collision. Upon collision, the ions, which have had a drift velocity in the electric field before collision, transfer some of their momentum and directed energy to the molecules. Then, in their next free path, they reattain the necessary drift velocity. The drift velocity immediately after collision will not be zero, but will be much less than the average drift velocity which ions have from one collision to the next. Consequently, assume that immediately after collision, the ions have completely "forgotten" that they were in an electric field, and the distribution of speeds may be taken as Maxwellian. Hence[12]

$$cf(c)dc=4\pi\left(\frac{m}{2\pi kT}\right)^{3/2}c^3\exp(-mc^2/2kT)dc \tag{5}$$

Defining

$$\xi=1/2\,\frac{mc^2}{kT} \tag{6}$$

yields

$$cf(c)dc=\frac{2}{\sqrt{\pi}}\left(\frac{2kT}{m}\right)^{1/2}\xi e^{-\xi}d\xi$$

Now,[13]

$$\frac{2}{\sqrt{\pi}}\left(\frac{2kT}{m}\right)^{1/2}=\bar{v}=\text{average speed of Maxwellian distribution}$$

so that $cf(c)dc=\bar{v}\xi e^{-\xi}d\xi$ and if $g=1/2\,mc_m^2/kT$, then

$$\int_{c_m}^{\infty}cf(c)dc=\bar{v}\int_{g}^{\infty}\xi e^{-\xi}d\xi \tag{7}$$

From the earlier definition of c_m, g may be seen to be the (dimensionless) kinetic energy required for an ion to travel from a point in space to the point on the particle at dS, just reaching dS with zero kinetic energy. The value of g may be determined by equating this kinetic energy to the energy required to travel in the potential fields existing, from P to dS. If ϕ is the electric potential at P and $\psi=e\phi/kT=$ dimensionless potential energy of ion at P, then, when $\psi_0-\psi\geq 0$

$$g=\psi_0-\psi \tag{8}$$

where $\psi_0=\psi$ at dS on the particle surface.

It may be seen that the lowest value which the lower limit of the integral of equation 7 is allowed to take on is zero; it cannot be a negative quantity since there cannot be more ions leaving from P for dS than the entire number which have had a collision at P and are headed for dS. Thus if the quantity $(\psi_0-\psi)$ should be negative, then g is replaced with zero in equation 7. The physical meaning of a negative g is evident from a consideration of the way in which the problem was developed. If an ion is moving against the field (assuming positive ions) it must have an initial velocity greater than zero to make any progress in the direction in which it started. If an ion first travels with the field and later against it, the energy which it gained in the first part of its trip will enable it to travel further through the repelling field. Or, stated in a different way, it may travel the same distance starting with a lower initial velocity. An ion which starts for the particle with zero velocity, and which travels a sufficient distance in the direction of the field, will have a residual velocity when it strikes the particle. Therefore, all ions headed towards dS which come from those regions in space where g is negative have sufficient velocity to reach the particle (although they may not actually reach the particle due to a collision). Thus

$$\bar{v}\int_{g}^{\infty}\xi e^{-\xi}d\xi=\begin{cases}\bar{v}(1+g)e^{-g} & \text{if } \psi_0-\psi\geq 0\\ \bar{v} & \text{if } \psi_0-\psi<0\end{cases} \tag{9}$$

The factor $(1+g)e^{-g}$ is thus seen to be the fraction of ions which have had a collision at P and have sufficient velocity to reach the particle. Fig. 3 shows a plot of this function versus g.

Minimum Ion Energy Under Influence of Uniform External Field

The problem of determining the potential in the neighborhood of a dielectric sphere in a uniform electric field is straight forward and may be found in any advanced text.[14] For the region outside the sphere the potential is

$$V=E_0\cos\theta\left[R-\frac{a^3}{R^2}\,\frac{(D_p-1)}{(D_p+2)}\right] \tag{10}$$

where D_p is the dielectric constant of the particle. The angle θ is shown in Fig. 2, along with other pertinent variables. These variables are related by rather complicated geometrical equations given in reference 8.

The total potential is the superposition of the potential of the charged particle and that given by equation 10. Since the potential due to the charge on the particle is $V=ne/R$, the potential energy of the ion in dimensionless form is

$$\psi=\frac{\gamma}{x}+w\left(x-\frac{\alpha}{x^2}\right)\cos\theta \tag{11}$$

$$x=\frac{R}{a},\quad w=\frac{eE_0a}{kT},\quad \alpha=\frac{D_p-1}{D_p+2},\quad \gamma=\frac{ne^2}{akT}$$

$$\psi_0=\gamma+w(1-\alpha)\cos\theta_E$$

The function $\psi_0-\psi$ is complicated and hence difficult to visualize, since it depends both on the position of the ion considered and the position of the element dS on the particle. Therefore it shall be examined here only for a few simple cases, namely the cases relative to the top T (i.e., considering dS to be situated on the top, where $\theta_E=0$); the bottom B ($\theta_E=\pi$); and the side S ($\theta_E=\pi/2$). For further analysis see reference 8. The set-up of the equations so far has implicitly assumed that the ions are positively charged, thus experiencing forces in the direction of the electric fields. The case of negative ions may be easily handled by changing the sign of e, the electronic charge. It is seen that the effect of doing so is to leave γ unchanged but to change w to $-w$. Thus, statements concerning θ_E will be reversed for negative ions, $\theta_E=0$ becoming $\theta_E=\pi$, and vice versa.

POTENTIAL ENERGY RELATIVE TO THE TOP

Consideration of the potential energy function relative to the top T shows that, at distances sufficiently far from the particle, an ion starting from rest gains energy from the external field to overcome the repelling field of the particle, and

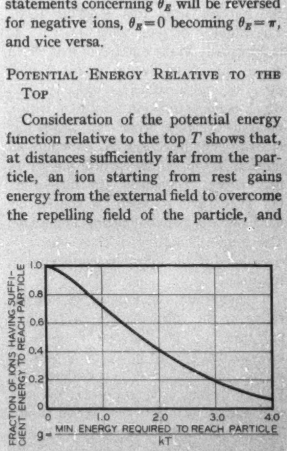

Fig. 3. Fraction of ions having sufficient energy to reach particle versus minimim ion energy required to reach particle

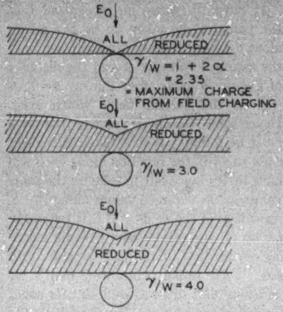

Fig. 4. Boundary of points for which all ions have sufficient energy to reach top (T) of particle. For various charge-to-field ratios

therefore $\psi_0-\psi<0$. This situation may be visualized by considering a surface representing the points from which an ion with zero speed at the boundary of the surface would reach dS with just zero speed. Ions which leave with zero velocity from points further from the particle than this surface will arrive at dS with a speed greater than zero.

The equation of this surface may be obtained by setting $g_{top}=0$, and the resulting relation defines the surface for any ϕ_r. The boundary can be drawn as shown in Fig. 4 for some typical values of γ/w with $\alpha=0.675$. For dioctylpthalate smoke whose dielectric constant is 7.2, $\alpha=0.675$. This smoke was used by the recent experimenters; see references 6 and 7. Analytical expressions and curves of the boundary of the sketches of Fig. 4 are presented in reference 8.

Those ions which leave from the region close to the particle marked "reduced" must have a velocity above some minimum in order to have a chance to reach dS; consequently only a fraction of the velocity distribution function is being counted, and this region will therefore be called the "reduced" region. The region on the other side of the boundary further from the particle is marked "all" since the entire distribution of velocities has a chance to reach dS if they leave from this region. The word "chance" is used here since there is still a probability that a collision with a molecule may occur between P and dS.

For 35 charges on an 0.15-micron radius particle ($\gamma=13.3$) and an external field of 5 kv/cm (per centimeter) ($w=2.85$), it is found that the boundary of the "all" region for $\theta_r=0$ is about 2.8 radii from the surface ($x=3.8, \theta_r=0$). This is the closest point at which all the ions have sufficient velocity to reach the particle. At 2.8 radii from the surface with zero external field, only 0.06% of the ions have speeds high enough to overcome the particle field. Thus the ratio of these is seen to be about 1,700 i.e., 1,700 times more ions have sufficient energy to reach the particle from a distance of 2.8 radii in the presence of a field of 5 kv/cm than do so without this field. Now, if the mean free path were long enough so that an appreciable number of these might survive on their trip to the particle, this effect would cause a large increase in the charging rate. For molecular ions at atmospheric pressure, the mean free path is such that only about 10^{-13} of the ions which are capable of reaching the particle, from 2.8 radii away, will actually arrive. Hence it may be seen that the increased energy effect will be small for molecular ions at atmospheric pressure.

A higher charge was found by Penney and Lynch for charging by means of negative corona at high wire potentials. They proposed that this could be due to the presence of some free electrons as well as negative ions at voltages near breakdown. It is instructive to look at the energy effect of the field on electrons. For electrons whose mean free path is much longer than ions, about 36% of the electrons can travel from 2.8 radii away without a collision, compared to 10^{-13} of the ions. Thus it is seen that the presence of the external field can produce an extremely significant increase in the charging rate from the ion energy effect when mean free paths of the order of the particle radius or larger are encountered. However, for usual molecular ions at atmospheric pressure, one must look for the major field effect to come from increased ion density close to the particle for all but the very smallest particles.

POTENTIAL ENERGY RELATIVE TO THE BOTTOM

The quantity g is always positive and it increases monotonically with distance from the particle. There are no boundaries, such as in Fig. 4, for the bottom B of the particle; g is always greater when an external field is present than it would be with no external field; therefore there will be fewer ions capable of reaching the particle from the bottom when the field is present.

POTENTIAL ENERGY RELATIVE TO THE SIDE

Relative to the side S, it may be determined that for $\pi/2<\phi_r<3\pi/2$, g may become negative while for $3\pi/2<\phi_r<\pi/2$, g is always positive. The region $\pi/2<\phi_r<3\pi/2$ is above the equator of the sphere, while the other region is below. This will then result in a boundary which can be pictured as in Fig. 5 for the plane $\phi_r=0, \pi$. For this case the effect of the field is to increase charging from the planes $\pi/2<\phi_r<3\pi/2$ and decrease it for $3\pi/2<\phi_r<\pi/2$.

SUMMARY OF EFFECT OF EXTERNAL FIELD ON ION ENERGY

1. Near the top of the sphere, ions heading toward the particle travel in the direction of external field, thereby gaining energy, and increasing the number of ions which have sufficient energy to reach the particle.
2. Near the bottom of the sphere, ions heading toward the particle travel against the field, thereby losing energy, and decreasing the number of ions which have sufficient energy to reach the particle.
3. Around the equator of the sphere, ions heading toward the particle from above travel with the main field, while ions from below travel against the main field. Thus it seems that the net effect on the side should be little different from the case of zero external field, which is reasonable since the total field is purely radial and equal to the particle field for $\theta_r=0$.

Effect of Electric Field on Ion Density

The ion density N in equation 4 must be known as a function of position in order that the integration be carried out. The particular form of the density distribution is determined by the particular fields which exist. However, a general equation for the ion density may be written for arbitrary fields.

The controlling partial differential equation for the ion density in a force field may be derived by considering the total net ion current and the conservation of matter. On the one hand, there is a simple diffusion of ions whose flow is proportional to the concentration gradient. On the other hand, there is a flow at every point proportional to, and in the

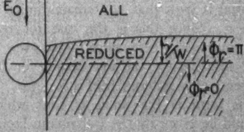

Fig. 5. Boundary of points for which all ions have sufficient energy to reach side (S) of particle

direction of, the electric field. When a field exists which attempts to disturb the density from a uniform distribution (such as the action of a charge on the particle because of the repelling action of this charge on the like-charged ions surrounding the particle), the diffusive flow comes into action in an attempt to return the distribution to uniform. In the steady state (if it is ever reached) there is a counterbalancing of these two effects which must meet whatever net flow conditions are prescribed by any external fields which may be present. This derivation is given in reference 8 along with the required boundary conditions. This equation is of the form given by Jost[15] as the equation of diffusion under the influence of external forces. To solve this exact equation with the specified boundary conditions is a formidable task. Approximations are also discussed in reference 8, where it is shown that it is reasonable to assume a steady state in time when solving for the ion density distribution and also to assume that there is zero flow of ions to the particle for purposes of determining the density. With these assumptions the diffusion equation for determining ion density is

$$\nabla^2 N + \nabla\psi \cdot \nabla N = 0 \tag{12}$$

$N \rightarrow N_0$ = ion density at infinite distance from particle as $x \rightarrow \infty$ for all θ

$$\text{grad}_x\, N + N\, \text{grad}_x\, \psi = \frac{\partial N}{\partial x} + \frac{\partial \psi}{\partial x}\, N = 0 \text{ at } x = 1$$

$$\nabla^2 N = \frac{1}{x}\frac{\partial^2}{\partial x^2}(xN) + \frac{1}{x^2 \sin\theta}\frac{\partial}{\partial \theta}\left(\sin\theta \frac{\partial N}{\partial \theta}\right) \tag{13}$$

$$\nabla_x N = \frac{\partial N}{\partial x};\ \nabla_\theta N = \frac{1}{x}\frac{\partial N}{\partial \theta}$$

where

$$x = R/a;\quad \psi = \gamma/x + w(x - \alpha/x^2)\cos\theta$$

It may be seen that a solution of equation 12, which satisfies the boundary condition at the particle surface, is exponential $(-\psi)$. (This is true regardless of the form of ψ.) However, the boundary condition at infinity will be satisfied by this function only if the potential is such that $|\psi|$ remains finite as $x \rightarrow \infty$. Since this is the case for zero external field where, since $w = 0$, $\psi = \gamma/x$, the solution for the ion density in the absence of an external field is $N = N_0 e^{-\gamma/x}$. This form is the same as that which would be given by the Boltzmann factor from the kinetic theory of reference 16, and is the ion density used by White (only to evaluate the density at the particle surface, however). This result is to be expected since the steady state in the absence of an external field with no flow to the particle is an equilibrium situation and meets the conditions of the Boltzmann derivation.

Attempts at a mathematical solution of this problem for the potential given in equation 13 were unsuccessful. In the light of the availability of an IBM *650* (International Business Machines Corporation) computer and a small amount of time on an IBM *704*, a solution of equation 12 based on finite difference approaches was believed feasible. Many different attacks along the finite difference line were attempted but a complete solution was never attained. It was found that an extremely large number of points (resulting in a large number of simultaneous linear equations) would be required to obtain a solution of modest accuracy. These mathematical and finite difference approaches are described in detail in reference 8.

Due to the complexity of this problem it is necessary to build up evidence about the nature of the solution and the magnitude of the effect of the external field on the ion density, and therefore on the charging rate and final charge. The type of effect may be seen by considering that the charge on the particle attempts to cause a current flow outward from the particle while the external field attempts to cause a current flow toward the particle on the top, and away from the particle on the bottom. Hence, the external field should cause an increase in ion density at the top of the particle and a decrease at the bottom. An estimate of the magnitude of the effect will be made by means of finite difference approximations along $\theta = 0$, where the particle and external fields oppose each other; the major increase in density occurs there. The details of the mathematical basis for these approximations are given in reference 8; a brief description of the basic ideas of the method is given here.

Finite difference equations written for the points on the ray $\theta = 0$ are relations between the functional values of ion density along this ray and the functional values along the next closest ray (which will be designated ray k) in the direction of increasing θ. If values are known for the points along ray k, the form of the equation is such that a direct solution (not one by iteration) can be made for the unknowns along $\theta = 0$. Various values were assumed for the points on ray k with the intention of determining how much of an increase the external field would cause in the ion density near the surface of the particle at $\theta = 0$.

It must of course be recognized that the values to be taken on by the points along $\theta = 0$ are directly dependent on both the assumed values at k and the distance of the ray k away from the ray $\theta = 0$, as well as the various fields which exist. Hence some reasonable value for the ray k must be found. If it is taken extremely close to $\theta = 0$, the function along $\theta = 0$ will have little choice but to take on the same values as the assumed values along ray k, regardless of the fields. If it is taken too far away, the results may become meaningless because of the large angular-grid size. Fifty radial points were used after verifying that this was sufficient for small trunation error by comparing with results for 100 points. By means of a lengthy

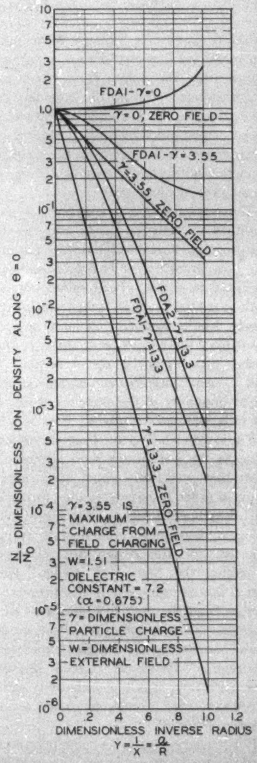

Fig. 6. Results of finite difference approximations for various particle charges. Typica case for $\gamma = 13.3$, $w = 1.51$: 35 charges on 0.15-micron radius particle in a field of 2.65 kv/cm

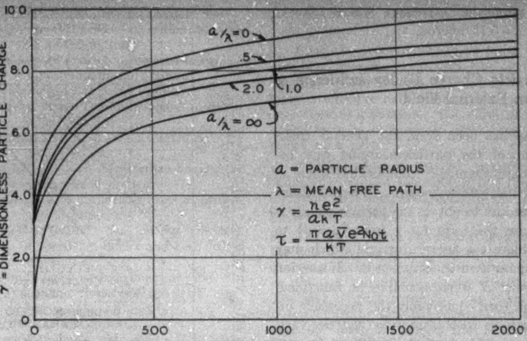

Fig. 7 Particle charge in absence of an external field for various ratios of particle radius to mean free path

series of trials, explained in reference 8, $\theta=\theta_k=25$ degrees was selected as a conservative value. If a θ greater than 25 degrees were chosen, the results for ion density would be higher.

Two solutions for two sets of values assumed along ray k are proposed. These will be denoted as FDA (finite difference approximations) 1 and 2. They are presented in an attempt to give limits for the density. The first, FDA 1, is found by assuming the values along ray k to be that which would exist at all angles in the absence of an external field, i.e., the values given by the Boltzmann factor $N_0e^{-\gamma/x}$. This value is known to be too low, and these results are proposed as a conservative estimate (conservative because $\theta_k=25$ degrees and not larger was used, and because $N_k=N_0e^{-\gamma/x}$ is an obviously lower value than actual) for a lower limit on the ion density along $\theta=0$ for an external field of the magnitude used.

FDA 2 is obtained as a conservative upper limit by allowing the values along ray k to be given by $N_k=N_0e^{-Ky}$, where K was varied from γ to zero (this is seen to be of the form of the Boltzmann factor but it really has no physical significance here, except for the case $K=\gamma$). As K is reduced the values along ray k become larger and, as would be expected, the values along $\theta=0$ also increase. For very small K, the values along $\theta=0$ become less than those along ray k, which is a physical impossibility. Hence the values found along $\theta=0$, when the surface value at $\theta=0$ is equal to the surface value at $\theta=\theta_k$, where taken as an upper limit and are referred to as FDA 2.

Fig. 6 shows the results of FDA 1 and 2 with a comparison with the zero field case for $\gamma=13.3$, $w=1.51$, $\alpha=0.675$. A typical case for these values is 35 charges on a 0.15-micron radius particle in an external field of 2.65 kv/cm. It may be seen that the factor by which the ion density at the particle surface at $\theta=0$ is increased due to the presence of the external field is between 130 and 440, as shown by the points for $y=1.0$ in Fig. 6.

It may be seen from the other curves of Fig. 6 that the increase over the Boltzmann factor caused by the field is a function of the charge on the particle as well as the external field. These curves are for the same external field but a charge on the particle equal to the saturation charge from field charging $\gamma=(1+2\alpha)w$ and a charge of zero determined by FDA 1. For the case of $\gamma=3.55$, $w=1.51$, we see that the field now causes an increase of only a factor of 5 over the Boltzmann factor compared to the lower limit of 130 for $\gamma=13.3$. For zero charge on the particle, the curve for $w=1.51$, $\gamma=0$, shows an increase over the Boltzmann factor (which is 1.0 everywhere for $\gamma=0$) as a factor of only 2.5. This shows that the factor of increase over the zero field value is greatly dependent on the particle charge as well as the external field present.

Lastly, one calculation was made at $\theta=180$ degrees to determine the order of magnitude by which the ion density is decreased by the field, which at $\theta=180$ degrees is in the same direction as the particle field. The results for FDA 1 (with the ray k now 25 degrees away from $\theta=180$ degrees) showed that the charging contribution from the lower part of the particle will be very small; a factor of decrease of 2.8 less than the zero field value being found. In addition, since the factor of decrease at $\theta=180$ degrees is far less than the factor of increase at $\theta=0$, the higher density demonstrated to be present at $\theta=0$ may exist over a considerable portion of the particle so that the average density may be considerably higher than just a simple average of the top and bottom densities would indicate. Since the approximations are based only on the behavior at $\theta=0$ and 180 degrees, one cannot more closely estimate this increase in average ion density.

SUMMARY OF EXTERNAL FIELD EFFECT ON ION DENSITY

From the previous discussion the following tentative conclusions may be drawn. The effect of the external field on the ion density is a very strong one. The density is increased over the zero field value where the external field opposes the particle field and decreased from the value where they are in the same direction. Results will be quoted for an external field of 2.65 kv/cm with 35 charges on a 0.15-micron particle of dielectric constant of 7.2, unless otherwise stated.

1. The lower limit of decrease at the surface at $\theta=180$ degrees is only about a factor of 2.8 less than the zero field value compared to a lower limit of increase at $\theta=0$ of 130. This indicates that the increase around $\theta=0$ may exist over an appreciable area.
2. The order of magnitude of increase at the surface at $\theta=0$ is conservatively from 130 to 440 times the zero field value.
3. The increase at $\theta=0$ varies with charge on the particle as well as with the external field. For an external field of 2.65 kv/cm the factor of increase over the zero field case at the surface given by the lower limit given is: 2.5 for an uncharged particle; 5 for 9 charges (which is the saturation charge from field charging); and 130 for 35 charges.

Particle Charge in Absence of an External Field

It is possible to perform a complete analytical solution for the zero field case with the use of equation 4 since N is given by the Boltzmann factor and g is sufficiently simplified that all integrations may be performed. The particle charge is found to depend on the mean free path (pressure effect) in a manner such as that shown in Fig. 7. The curve for zero mean free path ($a/\lambda=\infty$) is that given by White. This variation with pressure has not appeared in previous theories. The earlier discussion of the energy effect showed that the pressure variation will be larger when an external field is present although not paticularly significant for molecular ions at atmospheric pressure where $a/\lambda = 11$ for $a = 0.15$ micron.

Particle Charge Under Influence of an External Field

As has been seen, the general treatment of the particle-charging rate bebecomes extremely complicated when an external field is present. The necessary procedure to obtain the particle charge is to use the form for g from $(\psi_0 - \psi)$ to evaluate the energy integral which may then be used in equation 4. If the ion density N were available in functional form, then conceivably the necessary integrations with respect to the space variables could be performed with the form of the integrand changing whenever g went negative. Once this result is available, the total charging rate can be obtained by an integration over the surface of the particle

$$\frac{dn}{dt} = \int_S \frac{dn}{dt}\bigg|_{dS} = 2\pi a^2 \int_0^{\pi} d\theta_E \times \sin\theta_E \left\{ \frac{1}{dS} \frac{dn}{dt}\bigg|_{dS} \right\} \tag{14}$$

since $dS = a^2 \sin\theta_E d\theta_E d\phi_E$, where the integration with respect to ϕ_E gives 2π, since the integrand is independent of ϕ_E.

Certainly, because of its complexity, this procedure is to be avoided if possible. As will be remembered, the mean free path for ions is of the order of one tenth the particle radius, or less for particles of a 0.15-micron radius and larger. This leads to the conclusion that only those ions which have collisions very near the particle will be the ones that actually attach to the particle. That is, there is a little increase in the charging rate from the ion energy considerations, since ions come from very close to the particle, so they are able to acquire little increase in energy from the field. The important factor in determining the increased charging for molecular ions will be the ion density at the surface of the particle. (It is noted earlier that, for electrons, the energy effect is extremely important.) Hence it is proposed that the main effects for ions can be explained by calculations made on the basis of the limiting case of zero mean free path.

In the limit of zero mean free path, g becomes zero and the integrations may be performed giving

$$\frac{dn}{dt}\bigg|_{dS} = \frac{\bar{v} dS}{4} N_s \tag{15}$$

where N_S = ion density at the surface of the particle. Defining a dimensionless product of ion density and time as

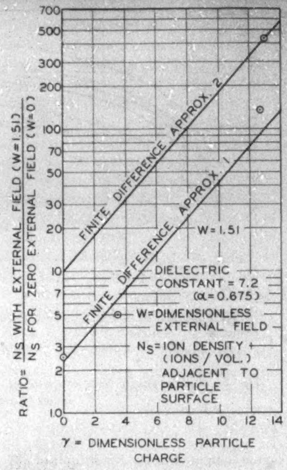

Fig. 8 Effect of external field on ion density at top of particle ($\theta = 0$) as function of particle charge. Typical case same as for Fig. 7

$$\tau = \frac{\pi a \bar{v} e^2 N_0 t}{kT}$$

gives the total charging rate as

$$\frac{d\gamma}{d\tau} = \frac{1}{2 N_0} \int_0^{\pi} d\theta_E \sin\theta_E N_s$$

This integral may be recognized as the average value of N_s over the surface of the particle, so

$$\frac{d\gamma}{d\tau} = \frac{N_{s(\text{avg})}}{N_0} \tag{16}$$

If it is assumed that about one half of the particle area has a surface ion density of the order of that at $\theta = 0$ and the other half has negligible charging, the average ion density over the particle surface is one half of that at $\theta = 0$. This factor of one half seems reasonable from earlier considerations, comparing the increase of density of $\theta = 0$ and the decrease at $\theta = 180$ degrees, which showed the lower limit of decrease at 180 degrees to be a factor of about 2.8, compared to a lower limit of increase at $\theta = 0$ of 130.

An approximate equation may be obtained from the results by a consideration of the factor of increase in ion density over the Boltzmann factor, as shown in Fig. 8, in which are plotted the factor of increase at $\theta = 0$ versus γ, the dimensionless charge on the particle for $w = 1.51$, and $\alpha = 0.675$ for the few tests which apply. It may be seen that the three points for FDA 1 tend to fall on a straight line on this semilogarithmic scale. The straight line is proposed as an estimate of the variation with charge of the factor of increase over the Boltzmann result for the particular values $w = 1.51$ and $\alpha = 0.675$. It may be seen from Fig. 1 that our prediction that the increase in ion density should be less for lower charges is in general agreement with the experimental results. For example at, say, 30 charges on the particle, the experimental rate is only a factor of 400 higher than the Boltzmann factor result, compared to the factor of 2,600 higher at 35 charges. Assuming the same sort of variation with γ for FDA 2 the upper curve of Fig. 8 may be obtained by drawing a line parallel to the lower line through the one data point at 440.

A straight line on the logarithmic plot is an exponential variation, of course, and the equations of the two lines are

$$\text{FDA } 2 = 10\, e^{+0.3\gamma}$$
$$\text{FDA } 1 = 2.2\, e^{+0.3\gamma}$$

and using the factor of one-half for the average ion density yields the following for the charging rate for $w = 1.51$, $\alpha = 0.675$:

$$\left(\frac{d\gamma}{d\tau}\right)_{\text{FDA2}} = 5e^{+0.3\gamma} e^{-\gamma} = 5e^{-0.7\gamma}$$

$$\left(\frac{d\gamma}{d\tau}\right)_{\text{FDA1}} = 1.1e^{+0.3\gamma} e^{-\gamma} = 1.1e^{-0.7\gamma} \tag{17}$$

A general equation of the form $d\gamma/d\tau = K_1 e^{-K_2\gamma}$ may be seen to integrate into

$$\gamma = \frac{1}{K_2} \ln(e^{K_2\gamma_0} + K_1 K_2 \tau) \tag{18}$$

where $\gamma = \gamma_0$ when $\tau = 0$.

The curves marked as FDA 1 and 2 in Fig. 1 were plotted from equation 18 with the use of K_1 and K_2 from equation 17. Also plotted in dashed lines are the respective FDA 1 and 2 obtained by assuming only one third of the particle area to have the increase at $\theta = 0$, and two thirds having negligible charging. It is seen that this assumption is not too critical since the 33% decrease in area from 1/2 to 1/3 caused only about a 4% decrease in charge at $N_0 t = 14 \times 10^{-7}$ and a 5% decrease at $N_0 t = 1 \times 10^{-7}$ for FDA 2.

Conclusions

It is seen that an increase in the ion density of the order of magnitude indicated here will explain the reason for the discrepancy between experiment and the previous theory for charging by positive corona at atmospheric pressure for particles in the size range around a 0.15-micron radius. This is particularly true when it is remembered that the increase may well be larger than is found from FDA 2 due to the conservative choice of $\theta_k = 25$ degrees. In addition, there will be a slight increase due to the finite but small mean free path which was called zero in approximation. It is believed that a more accurate determination of the ion density, perhaps by means of a complete finite difference solution, will bear out the general nature of the results stated here. The indications presented do show that a large effect exists due to the presence of the field; and this effect must be taken into account in some manner for a reasonably accurate determination of the particle charge.

In the case of charging by negative corona at higher wire potentials at atmospheric pressure, the results on the energy effect of the field show that if free electrons are present, even in an amount which is a small fraction of the number of negative ions, they may materially increase the particle charge. Little more than this may be said at present, since it is not known in what ratio free electrons would exist. Further work along this line would have to be done to indicate the magnitude of increase more accurately. The field effect on the density will be much less important for electron charging because of the longer free path which means that electrons come from distances at which the density is not very different from that at infinity.

The theory has the inherent capability of including variations with pressure by means of the variation of charge with mean free path of ions. The results of Fig. 7 for zero external field show this variation. This effect will be larger when the external field is considered and may be included if several numerical integrations are performed.

Nomenclature

Basic Quantities

a = particle radius, cm
n = number of electronic charges on particle
E_0 = uniform external field strength, statvolts/cm
e = electronic charge, 4.8×10^{-10}, statcoulombs
N_0 = ion density in absence of charged particles, ions/cc (cubic centimeters)
t = time measured from start of charging, sec (seconds)
D_P = dielectric constant of particle
T = absolute temperature, K (degrees Kelvin)
k = Boltzmann's constant = 1.381×10^{-16} erg/K
dV = infinitesimal volume at P, cm^3
R = distance from center of particle to P, cm
dS = infinitesimal area on particle, cm^2
x_r, y_r, z_r = Cartesian co-ordinates with dS as origin, cm
r, θ_r, ϕ_r = spherical co-ordinates for x_r, y_r, z_r system, cm, rad (radians)
N = ion density at point P, ions/cc
c = speed of ion (without regard to direction), cm/sec
λ = mean free path of ions colliding with molecules, cm
= 1.3×10^{-6} cm (indefinite) for ions at atmospheric pressure
= 4.1×10^{-5} cm for electrons at atmospheric pressure
$f(c)dc$ = probability that an ion will have a speed between c and $c+dc$ after collision
c_m = minimum speed which an ion can have at P and still reach dS, cm/sec
m = mass of ion, grams
$\bar{v}$ = average ion speed; 4.63×10^4 cm/sec for $T = 300$ K
x_E, y_E, z_E = Cartesian co-ordinates with center of sphere as origin, with E_0 parallel to z_E, cm
θ_E, ϕ_E = spherical co-ordinates for x_E, y_E, z_E system, rad
ϕ = electric potential, total, statvolts
V = electric potential, partial, statvolts
θ = angle between radius vector R and external field direction, rad
θ_k = value of θ for which the ion density was given assumed values, rad
N_s = ion density at the particle surface, ions/cc
$N_{s\,avg}$ = ion density averaged over the particle surface, ions/cc

Dimensionless Quantities

$\gamma = ne^2/akT$ = dimensionless (dml) charge on particle
γ_0 = initial dml charge on particle at time = zero
$w = eE_0a/kT$ = dml external field strength
$\alpha = (D_P - 1)/(D_P + 2)$
$\xi = mc^2/2kT$ = dml kinetic energy of ion with speed c
$g = mc_m{}^2/2kT$ = dml kinetic energy of ion with speed c_m
$\psi = e\phi/kT$ = dml electrical potential energy at P
$x = R/a$ = dml radius from center of sphere to P
$y = 1/x$ = dml inverse radius
N_k = assumed values of N along θ_k
$\tau = \pi a \bar{v} e^2 N_0 t/kT$ = dml time
K_1, K_2 = constants, see equation 18

Appendix. Assumptions

In all of the work here the following assumptions are made:

1. Particles are spherical.

2. Particle size is small compared to particle spacing.

3. The mean free path of ions is constant, independent of ionic velocity.

4. Ion-ion collisions are highly improbable due to the large difference in ionic and molecular densities (i.e., 10^9 ions/cc versus 10^{19} molecules/cc), therefore the mean free path of ions is independent of ionic density and depends only on molecular density, which is determined by pressure.

5. Charge is uniformly distributed on particles so that their fields are those of point charges.

6. Image forces (the attractive forces on individual ions due to the dielectric, or conducting, particle) are neglected. This force is effective only when an ion comes very close to a particle. The effect of the image force is to increase the charge attained by a particle.

7. All ions which strike the particle are assumed to remain attached to it. Image force considerations would indicate that this is a good assumption.

8. The space charge of ions traveling from the active to the passive electrode in the charging chamber causes the current to be limited and stabilizes the discharge. The field existing in the charging chamber is determined by this space charge, the wire potential and, of course, the geometry. In many practical cases the space charge is by far the predominant effect. Introduction of a particle (which soon becomes partially charged) will cause a local redistribution of the space charge.

Since the particle density is generally small compared to the ion density and the region of influence of a particle is limited to its immediate vicinity, the effect of this redistribution of the ion density on the field will be small. Consequently, it will be assumed that the external fields which a particle experiences are given by the value which exists in the absence of the particle.

9. As noted earlier, particle charging occurs by means of two mechanisms: field charging and random-motion charging. The field-charging results are given by White[6]; they show that for small particles and appreciable charging times that this charge is small compared to the final charge attained while a particle is in the charging chamber. Consequently, it is assumed that the particle acquires a charge equal to the maximum value from field charging very quickly and this value is used as the initial charge for calculations of charging by random motion. This maximum charge from field charging is given by

$$n = \frac{a^2E_0}{e}(1+2\alpha)$$

10. It will be assumed that ions travel in straight lines from collision to collision; i.e., the fields present cause negligible bending of the trajectories. This is partially justified by the fact that the majority of ions of interest travel nearly parallel to the field lines. In addition, any ions which do not hit the particle because of a curved path will have a mate, which, if it traveled in a straight line would miss the particle, but due to the curved path may well arrive at the particle. Thus there is a tendency for compensating effects due to curved paths. The inclusion of curved paths in the theory would result in extreme mathematical complication.

THE MANUFACTURE of components for a system as complex as the computer manufactured by IBM (International Business Machines Corporation) Kingston for use use in the SAGE (Semiautomatic Ground Environment) System requires strict adherence to specified requirements. To meet these requirements, analysis and control of vast numbers of fabricating operations are essential. These operations, although minor in themselves, can jeopardize the effective and specified function of the entire computer by their cumulative shortcomings.

Due to the size and complexity of the SAGE computer, which contains more than 7,371 pluggable units (each having approximately 450 solder connections), 50,000 vacuum tubes, 170,000 diodes, and 600,000 resistors, the problem of developing quality assurance procedures applicable to the manufacture of these components is critical.

IBM has conducted intensive studies to assure that the manufacture of components for complex systems such as SAGE matches specified requirements. Results have shown that the standards of workmanship in all areas are being raised to meet the required quality levels by using a quality assurance procedure which employs the following fundamental principles:

1. Selection of a numerical basis for quality rating.
2. Classification of defects according to importance in component function and area of incidence.
3. Determination of the percentage limits of acceptability.
4. Planned audit inspection.
5. Planned master control.

The quality assurance procedure presently used by the quality engineering department of IBM Kingston is outlined in this report. The procedure is based upon the use of four charts on which the information listed in Table I is compiled and displayed.

It is the intent of this report to present a program which will: 1. develop a system for examining and rating each electromechanical component-manufacturing area and each product of these areas prior to sending the component to stock, and 2. determine the inspection efficiency for each inspection.

The main topics which are discussed are master control of manufacturing areas and audit control of material in stock. Interrelation of these two (including the inspection efficiency nomograph) is described separately. Derivations of all formulas are given in the appendixes.

Master Control of Manufacturing Areas

THEORY

To establish the master control system, the first consideration was to obtain a common denominator for the evaluation of all manufacturing areas. Because some manufacturing areas produce more complex subassemblies than others, a denominator had to be determined which would be equitable and applicable to all areas. This denominator is a complexity factor based upon the total number of solder joints produced by a manufacturing area; i.e., the more complex a subassembly, the more solder joints that subassembly will have, and from this, the denominator is determined.

The second consideration, also fundamental to the master control system, was the determination of the per cent-defective (based upon the total number of solder joints) allowable for each classification of defects. The classification of defects and the per-cent-defectives allowable in the end product as shown in Table II are the result of a special study initiated by the IBM Kingston quality engineering department.

Major solder defects include:

1. No solder at the joint.

Table I. Quality Assurance Charts

Name of Chart	Purpose	Information Displayed
Per-cent-defective	Reveals trouble areas of each classification of defects. A chart for each manufacturing area makes production supervisor aware of conformance of area to limits	Trend lines show the per-cent-defective within each defect class with respect to each limit line, including number and description of the most prevalent defects
Master rating control	Examines and rates each manufacturing area according to actual quality achieved	The per-cent-defective and quality rating of types of defects for each manufacturing area as disclosed by standard inspection procedures
Audit rating control	Examines and rates the product as sent to stock	The per-cent-defective and quality rating of types of defects passed into stock as disclosed by audit inspection
Inspection efficiency nomograph	Determines the inspection efficiency of each inspection area	Inspection efficiencies with respect to master control rating for each inspection area

Paper 59-144, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted March 18, 1958; made available for printing December 1, 1958.

R. A. HULNICK, H. G. HARDING, and J. T. ROWINSKI are with International Business Machines Corporation, Kingston, N. Y.

Table II. Classification of Defects and Allowable Per-Cent-Defective

Defect Classification	Allowable Per-Cent-Defective, %
Major solder	0.0075
Other major	0.01
Minor	0.03

2. Cold solder (crystallized and without feathering at the edges).
3. Loose solder (one or more wires unsecured and free to creep along the terminal).
4. Solder short (a tail or bridge connection between two conductors; not common).

Other major defects include damaged components, sheared wire strands, and components improperly mounted or improperly located.
